Rosen’s
Emergency Medicine
Concepts and Clinical Practice

Editor-in-Chief
Ron M. Walls, MD
Executive Vice President and Chief Operating Officer, Brigham Health; Neskey Family Professor of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Senior Editors
Robert S. Hockberger, MD
Emeritus Professor of Emergency Medicine, David Geffen School of Medicine at UCLA; Chair Emeritus, Department of Emergency Medicine, Harbor-UCLA Medical Center, Los Angeles, California

Marianne Gausche-Hill, MD, FACEP, FAAP, FAEMS
Medical Director, Los Angeles County EMS Agency; Professor of Clinical Medicine and Pediatrics, David Geffen School of Medicine at UCLA; EMS Fellowship Director, Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Katherine Bakes, MD
Associate Professor, Department of Emergency Medicine, University of Colorado School of Medicine; Clinical Director of Community Affairs, Director, At-Risk Intervention and Mentoring (AIM), Denver Health; Denver, Colorado

Jill Marjorie Baren, MD, MBE, FACEP, FAAP
Professor and Chair, Emergency Medicine, Perelman School of Medicine; Chief, Emergency Services, University of Pennsylvania Health System, Philadelphia, Pennsylvania

Timothy B. Erickson, MD, FACEP, FACMT, FAACT
Chief, Division of Medical Toxicology, Department of Emergency Medicine, Brigham and Women’s Hospital; Harvard Medical School, Boston, Massachusetts; Faculty, Harvard Humanitarian Initiative, Cambridge, Massachusetts

Andy S. Jagoda, MD
Professor and Chair, Department of Emergency Medicine, Icahn School of Medicine at Mount Sinai; Professor and Chair, Emergency Medicine, Mount Sinai School of Medicine, New York, New York

Amy H. Kaji, MD, PhD
Associate Professor, Emergency Medicine, David Geffen School of Medicine at UCLA; Vice Chair of Academic Affairs, Department of Emergency Medicine, Harbor-UCLA, Los Angeles, California

Michael VanRooyen, MD, MPH
Chairman, Emergency Medicine, Brigham and Women’s Hospital Professor, Department of Emergency Medicine, Harvard Medical School; Boston, Massachusetts; Director, Harvard Humanitarian Initiative, Harvard University, Cambridge, Massachusetts

Richard D. Zane, MD, FAAEM
The George B. Boedecker Professor and Chair, Department of Emergency Medicine, University of Colorado School of Medicine; Executive Director, Emergency Services, University of Colorado Health, Aurora, Colorado
Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.
To my wife Barb, thank you for the endless love, support, and patience and for being my closest and most trusted advisor. To my children, Andrew, Blake, and Alexa, thank you for making my life so complete that I can savor fully the joy and privilege of helping others. To David and Sharon Neskey, thank you for your vision and generosity in support of me and of our specialty. To my colleagues at Brigham and Women’s Hospital and the Department of Emergency Medicine at Harvard Medical School, thank you for the constant inspiration to drive toward excellence. To Peter Rosen and John Marx, thank you for showing the way with such extraordinary determination and clarity. And to Bob, Marianne, and our superb editors, you are the best team that one could hope for. Thank you for bringing so much brilliance, energy, and commitment to make this edition so special.

RMW

To Peter for his inspiration and mentorship over the years; to John for sharing his friendship and commitment to excellence; to Ron for his leadership and renewed vision for the “bible” of Emergency Medicine; to Marianne for her creativity and endless enthusiasm; to Amy, Andy, Jill, Katie, Mike, Tim, and Rich for their willingness to add this burden of love to their already busy lives; to Kate and Dee for their vigilance and professionalism; and to Patty, for bringing color and meaning to my life.

RSH

I would like to thank my family for their continued understanding of my work to improve emergency care. My husband David and our three children Katie, Jeremiah, and Sarah provide the love, joy, and encouragement that makes participation on endeavors as important as this text worthwhile. Finally, I would like to thank Drs. Ron Walls, Robert Hockberger, and all the associate editors for their incredible leadership in the creation of a truly state of the art textbook.

MGH

I am forever grateful to my husband Kenneth and my two sons, Noah and Andrew, for their everlasting love and for their tolerance of my long hours and work passions. I love you all so much. Mom and Dad—thanks for such a great start in life and for continuing to tell me how proud you are. It makes a difference, no matter how old you get. I have deep appreciation for my authors and fellow editors who have enriched my knowledge of emergency medicine and strengthened my clinical practice through your outstanding contributions to this book.

JMB

I extend my thanks to Valerie, Camille, Isabelle, Celeste, Julian, and my parents. I also give appreciation to my mentors and colleagues in Emergency Medicine, Toxicology, Wilderness Medicine, and Global and Humanitarian Health, with special thanks to Paracelsus and Alice Hamilton.

TBE

To all the faculty, residents, and staff at the Mount Sinai Department of Emergency Medicine—their commitment to excellence in clinical care, teaching, and research inspires me every day. To Silvana, my wife and closest colleague, for her support and for keeping me focused on the important things in life. To Ron, for being a mentor throughout my career; and to John, whose memory lives forever.

ASJ

As a first-time section editor, I am grateful to Ron, Bob, and Marianne for their incredible mentorship and patience with me, and to Dee and Kate for their editorial guidance. This has been a tremendous learning experience and opportunity. Thank you!

AHK

With love and thanks to my family, ever patient and ever supportive. And especially to my daughter, Isabella VanRooyen, who is striving toward a career in medicine. May she be as fortunate as I was to find wonderful colleagues, inspiring mentors, and generous patients to lead her into a fulfilling career in a field that she loves.

MV

It is both humbling and a privilege to be associated with this text and those who started it all—Rosen, Marx, Walls, and Hockberger—the founders of our discipline.

Director, Pediatric Emergency Medicine, Department of Emergency Medicine, Maine Medical Center, Portland, Maine

James R. Miner, MD
Chief of Emergency Medicine, Hennepin County Medical Center; Professor of Emergency Medicine, University of Minnesota, Minneapolis, Minnesota

Alicia B. Minns, MD
Assistant Clinical Professor of Emergency Medicine, Emergency Medicine, UCSD, San Diego, California

Jessica Monas, MD
Clinical Assistant Professor, Emergency Medicine, University of Arizona College of Medicine, Phoenix, Arizona

Andrew A. Monte, MD
Associate Professor, Department of Emergency Medicine, University of Colorado School of Medicine, Aurora, Colorado

Gregory P. Moore, MD, JD
Faculty Emergency Medicine Residency, Madigan Army Medical Center, Tacoma, Washington

Gregory J. Moran, MD
Professor, Department of Clinical Emergency and Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California; Department of Emergency Medicine and Division of Infectious Diseases, Olive View-UCLA Medical Center, Sylmar, California

Raveendra S. Morchi, MD
Associate Professor in Emergency Medicine, Department of Emergency Medicine, Harbor- UCLA Medical Center, Torrance, California

Robert L. Mueleman, MD
Professor and Chair, Department of Emergency Medicine, University of Nebraska Medical Center, Omaha, Nebraska

Brittany Lee Murray, MD
Assistant Professor, Division of Pediatric Emergency Medicine, Emory University School of Medicine, Atlanta, Georgia; Honorary Lecturer, Emergency Medicine Department, Muhimbili University of Health and Allied Sciences, Dar es Salaam, Tanzania

Mark B. Mycyk, MD
Attending Physician, Emergency Medicine, Cook County Hospital; Research Director, Toxikon Consortium, Chicago, Illinois

Joshua Nagler, MD, MHPEd
Assistant Professor, Pediatrics and Emergency Medicine, Harvard Medical School; Fellowship Director, Division of Emergency Medicine, Boston Children’s Hospital, Boston, Massachusetts

Sidhant Nagrani, MD
Director of Residency Simulation, Emergency Medicine, Emory School of Medicine, Atlanta, Georgia

Anthony M. Napoli, MD
Associate Professor of Emergency Medicine, Department of Emergency Medicine, The Warren Alpert Medical School at Brown University, Providence, Rhode Island

Lewis S. Nelson, MD
Professor and Chair, Department of Emergency Medicine, New Jersey Poison Information and Education System, Rutgers New Jersey Medical School, Newark, New Jersey

Michael E. Nelson, MD, MS
Attending Physician, Emergency Medicine, NorthShore University Health System, Evanston, Illinois; Attending Physician, Emergency Medicine, Toxicology, Cook County Hospital Stroger), Chicago, Illinois

Robert W. Neumar, MD, PhD
Professor and Chair, Department of Emergency Medicine, University of Michigan Health System, Ann Arbor, Michigan

Kim Newton, MD
Associate Professor, Emergency Medicine, USC, Keck School of Medicine, Los Angeles, California
Thomas Nguyen, MD  
Associate Program Director, Emergency Medicine, Mount Sinai  
Beth Israel, New York, New York

James R. Nichols III, DO  
Assistant Professor, Assistant Director of Emergency Ultrasound,  
Emergency Medicine, University of Mississippi Medical  
Center, Jackson, Mississippi

James T. Niemann, MD  
Professor of Medicine, UCLA School of Medicine, Department  
of Emergency Medicine, Harbor-UCLA Medical Center,  
Torrance, California

Jenna K. Nikolaides, MD, MA  
Medical Toxicology Fellow, Toxikon Consortium, Chicago,  
Illinois

Kimberly Nordstrom, MD, JD  
Medical Director, Psychiatric Emergency Services, Department  
of Psychiatry, Denver Health Medical Center, Denver,  
Colorado; Assistant Professor, Department of Psychiatry,  
University of Colorado Anschutz Medical Campus, Aurora,  
Colorado

Richard M. Nowak, MD, MBA  
Emergency Medicine, Henry Ford Health System; Professor,  
Emergency Medicine, Wayne State Medical School, Detroit,  
Michigan; Clinical Associate Professor, Emergency Medicine,  
University of Michigan Medical School, Ann Arbor, Michigan

John F. O’Brien, BS, MD  
Attending Physician, Department of Emergency Medicine,  
Orlando Regional Medical Center; Associate Clinical  
Professor, Department of Emergency Medicine, University of  
Central Florida, Orlando, Florida; Associate Clinical  
Professor, Department of Surgery, University of Florida,  
Gainesville, Florida

Adedamola A. Ogunniyi, MD  
Faculty, Department of Emergency Medicine, Director, Process  
and Quality Improvement Program, Harbor-UCLA Medical  
Center, Torrance, California

Kelly P. O’Keefe, MD  
Program Director, Emergency Medicine, University of South  
Florida-Tampa General Hospital, Tampa, Florida

Edward Joseph Otten, MD  
Professor of Emergency Medicine and Pediatrics, Director,  
Division of Toxicology, University of Cincinnati College of  
Medicine, Cincinnati, Ohio

Leslie C. Oyama, MD  
Associate Clinical Professor, Emergency Medicine, University of  
California, San Diego, San Diego, California

Patricia Padlipsky, MD, MS  
Associate Clinical Professor of Pediatrics, David Geffen School  
of Medicine, University of California at Los Angeles, Los  
Angeles, California; Director, Pediatric Emergency  
Department, Harbor-UCLA Medical Center, Torrance,  
California

Daniel J. Pallin, MD, MPH  
Research Director, Department of Emergency Medicine,  
Brigham and Women’s Hospital; Assistant Professor,  
Department of Emergency Medicine, Harvard Medical  
School, Boston, Massachusetts

Linda Papa, MD, MSc  
Director of Academic Clinical Research, Professor of Emergency  
Medicine, Orlando Regional Medical Center; Professor,  
Department of Medicine, University of Central Florida,  
Orlando, Florida; Adjunct Professor, Emergency Medicine,  
University of Florida, Gainesville, Florida; Adjunct Professor,  
Neurology and Neurosurgery, McGill University, Montreal,  
Quebec, Canada

Ram Parekh, BA, MD  
Assistant Professor, Emergency Department, Icahn School of  
Medicine at Mount Sinai, New York, New York; Attending  
Physician, Emergency Department, Elmhurst Hospital  
Center, Elmhurst, New York

Asad E. Patanwala, PharmD  
Associate Professor, Pharmacy Practice and Science, The  
University of Arizona, Tucson, Arizona

David A. Peak, MD  
Assistant Residency Director, Harvard Affiliated Emergency  
Medicine Residency, Emergency Medicine, Massachusetts  
General Hospital; Assistant Professor, Emergency Medicine  
(Surgery), Harvard Medical School, Boston, Massachusetts

Ryan Anthony Pedigo, MD  
Director of Undergraduate Medical Education, Department of  
Emergency Medicine, Harbor-UCLA Medical Center,  
Torrance, California; Assistant Professor of Medicine, David  
Geffen School of Medicine at UCLA, Los Angeles, California

Debra Perina, MD  
Professor, Division Director, Prehospital Care, Regional Quality  
Director, Emergency Medicine, University of Virginia,  
Charlottesville, Virginia

Andrew D. Perron, MD  
Professor and Residency Program Director, Department of  
Emergency Medicine, Maine Medical Center, Portland, Maine

Shawna J. Perry, MD  
Associate Professor, Emergency Medicine, University of Florida  
College of Medicine-Jacksonville, Jacksonville, Florida;  
Honorary Associate Professor, CPQI, Department of  
Industrial Engineering, University of Wisconsin-Madison,  
Madison, Wisconsin

Michael A. Peterson, MD  
Assistant Professor, Department of Medicine, David Geffen  
School of Medicine at UCLA, Los Angeles, California;  
Director, Adult Emergency Department, Department of  
Emergency Medicine, Harbor-UCLA Medical Center,  
Torrance, California
James A. Pfaff, MD
Assistant Professor, Department of Military and Emergency Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Department of Emergency Medicine, San Antonio Military Medical Center, Staff Physician, San Antonio Uniformed Services Health Education Consortium, San Antonio Military Medical Centers, Fort Sam Houston, Texas

Camiron L. Pfennig, MD, MHPE
Associate Professor, Emergency Medicine, University of South Carolina Greenville; Residency Program Director, Emergency Medicine, Greenville Health System, Greenville, South Carolina

Melissa Platt, MD
Associate Professor, Emergency Medicine, University of Louisville, Louisville, Kentucky

Charles V. Pollack, Jr., MA, MD
Professor, Emergency Medicine, Sidney Kimmel College of Medicine; Associate Provost, Associate Dean for Continuing Medical Education, Thomas Jefferson University, Philadelphia, Pennsylvania

Trevor R. Pour, BA, MD
Assistant Residency Program Director, Department of Emergency Medicine, Mount Sinai Hospital, New York, New York

Timothy G. Price, MD
Associate Professor, Emergency Medicine, University of Louisville, Louisville, Kentucky

Michael A. Puskarich, MD
Associate Professor, Research Director, University of Mississippi Medical Center, Jackson, Mississippi; Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Tammie E. Quest, MD
Professor, Emory University School of Medicine, Department of Emergency Medicine; Director, Emory Palliative Care Center; Chief, Department of Veterans Affairs, Hospice and Palliative Medicine, Atlanta, Georgia

Elaine Rabin, MD
Icahn School of Medicine at Mount Sinai, New York, New York

Ali S. Raja, MD, MBA, MPH
Vice Chairman, Department of Emergency Medicine, Massachusetts General Hospital; Associate Professor of Emergency Medicine and Radiology, Harvard Medical School, Boston, Massachusetts

Rama B. Rao, MD
Assistant Professor, Chief, Division of Medical Toxicology, Department of Emergency Medicine, New York Presbyterian Hospital, Weill Cornell Medicine, New York, New York

Neha P. Raukar, MD, MS
Assistant Professor, Emergency Medicine, Warren Alpert Medical School of Brown University; Attending Physician, Emergency Medicine, Rhode Island-Miriam Hospital; Director, Emergency Medicine, Center for Sports Medicine, Providence, Rhode Island

Robert F. Reardon, MD
Professor, Department of Emergency Medicine, University of Minnesota; Faculty Physician, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

David B. Richards, MD, FACEP
Assistant Professor, Department of Emergency Medicine, University of Colorado School of Medicine; Director, Medical Student and Intern Clerkship, Department of Emergency Medicine, Denver Health Medical Center, Denver, Colorado

Ralph J. Riviello, MD, MS
Professor and Vice Chair of Clinical Operations, Emergency Medicine, Drexel University College of Medicine; Medical Director, Philadelphia Sexual Assault Response Center, Philadelphia, Pennsylvania

Daniel W. Robinson, MD
Assistant Professor of Medicine, Section of Emergency Medicine, Department of Medicine, University of Chicago Medicine and Biological Sciences, Chicago, Illinois

Howard Rodenberg, MD, MPH
Emergency Physician, Stormont-Vail HealthCare, Topeka, Kansas; Physician Advisor, Clinical Documentation Improvement, Baptist Health of Northeast Florida, Jacksonville, Florida

Chad E. Roline, MD
Department of Emergency Medicine, North Memorial Health Care, Robbinsdale, Minnesota

Genie E. Roosevelt, MD, MPH
Associate Professor, Emergency Medicine, Denver Health Medical Center, Denver, Colorado

Emily Rose, MD
Assistant Professor of Clinical Emergency Medicine, Department of Emergency Medicine, LA County + USC Medical Center, Keck School of Medicine of the University of Southern California, Los Angeles, California

Gabriel Rose, DO
Clinical Instructor, Department of Emergency Medicine, Mount Sinai St. Luke’s-Mount Sinai West Hospitals, New York, New York

Nicholas G.W. Rose, MD, PhD, FRCPC, Dip Sports Med (CASEM)
Clinical Assistant Professor, Department of Emergency Medicine, University of British Columbia, Vancouver, British Columbia, Canada

Tony Rosen, MD, MPH
Instructor in Medicine, Division of Emergency Medicine, Weill Cornell Medical College, New York, New York

Anne-Michelle Ruha, MD
Fellowship Director, Medical Toxicology, Banner Good Samaritan Medical Center, Phoenix, Arizona
Christopher S. Russi, DO
Chair, Division of Community Emergency Medicine, Department of Emergency Medicine; Assistant Professor of Emergency Medicine, Mayo Clinic, Rochester, Minnesota

Bisan A. Salhi, MD
Assistant Professor, Emergency Medicine, Emory University, Atlanta, Georgia

Arthur B. Sanders, MD, MHA
Professor, Emergency Medicine, University of Arizona, Tucson, Arizona

Genevieve Santillanes, MD
Assistant Professor, Emergency Medicine, Keck School of Medicine of the University of Southern California, Los Angeles, California

Richard J. Scarfone, MD
Associate Professor, Pediatrics, Perelman School of Medicine at the University of Pennsylvania; Attending Physician, Division of Emergency Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Carl H. Schultz, MD, FACEP
Professor of Emergency Medicine and Public Health, Director of Research, Center for Disaster Medical Sciences; Director, EMS and Disaster Medical Sciences Fellowship, University of California Irvine School of Medicine, Irvine, California; Director, Disaster Medical Services, Department of Emergency Medicine, University of California Irvine Medical Center, Orange, California

Jeremiah D. Schuur, MD, MHS
Chief, Division of Health Policy Translation, Department of Emergency Medicine; Vice Chair, Quality and Safety Clinical Affairs, Department of Emergency Medicine, Brigham and Women's Hospital; Assistant Professor, Department of Emergency Medicine, Harvard Medical School, Boston, Massachusetts

Professor and Chair, Emergency Medicine, Rosalind Franklin University of Medicine and Science-Chicago Medical School, North Chicago, Illinois; System Chair, Emergency Medicine, Sinai Health System, Chicago, Illinois
When we began planning for this ninth edition, we challenged ourselves to make substantial and meaningful improvements to a book that has become the trusted standard in our field. With broad and rapid changes occurring in health care and information sciences, we recognized that relevance is not an accidental or passive concept. To advance in relevance and consolidate the book's position as the defining reference in our specialty, we carefully and deliberately undertook bold changes that we know make the book at once fresh, directive, and current in a way we have never before dared.

First, we created a substantially enhanced role for our editors, one that would demand a great deal more of their time, creativity, and energy. This helped us build a substantially different team of editors, a perfectly balanced blend of those with great experience with prior editions and those who would bring new ideas and challenge our assumptions. Ron Walls was asked to serve as Editor-in-Chief, with Bob Hockberger in his long-standing role as senior editor. Marianne Gausche-Hill, a highly respected academic emergency physician with service as editor on four previous editions, stepped up to complete our senior editorial ranks. At the editor level, Dr. Andy Jagoda returns and is joined by six brilliant new editors drawn from academic programs from coast to coast—Drs. Katherine Bakes, Jill Baren, Timothy Erickson, Amy Kaji, Michael VanRooyen, and Richard Zane. This dynamic and innovative editorial team has dramatically redrawn our text's blueprint by preserving what has served our readers the best, such as well-written discussions of the pathophysiologic basis of illness and injury, while moving in entirely new directions in providing pithy, clear, and succinct recommendations for diagnosis and treatment.

We revisited page counts for every chapter, adjusting allocations where indicated, and added new chapters on several important topics. We focused anew on consistency and redundancy, enhancing the former and minimizing the latter. We moved some chapters to online access only, allowing us to add new topics of interest, such as drug therapy for older patients, and have provided a rich array of dynamic videos and images, especially in emergency ultrasound. We substantially expanded and reorganized the pediatric emergency medicine section, introducing dedicated pediatric chapters on airway management, procedural sedation, and drug therapy. We introduced significant new material on emergencies in the pregnant woman, the patient with cancer, and a variety of other highly important clinical conditions. And, in every possible case, we insisted on adherence to referencing and writing requirements, a focus on relevant directive information, and appropriate use of prose and illustrations to provide the perfect balance of depth, breadth, and ready accessibility.

We are enormously proud of the result, a different, more readable “Rosen,” preserving the gravitas earned over 30 years as the most important book in our specialty while embracing the modern era of emergency medicine practice and research and an entirely new generation of learners and practitioners. For those who have owned prior editions, we appreciate your loyalty over so many years and hope to reward it with a significantly improved and useful companion for your continuing learning and practice of this great specialty. For our newer readers, welcome, and thank you for inspiring us to make significant changes to an iconic and timeless part of our academic heritage.

Ron M. Walls
Robert S. Hockberger
Marianne Gausche-Hill
How This Medical Textbook Should Be Viewed by the Practicing Clinician and Judicial System

The editors and authors of this text strongly believe that the complex practice of medicine, vagaries of human diseases, unpredictability of pathologic conditions, and functions, dysfunctions, and responses of the human body cannot be defined, explained, or rigidly categorized by any written document. Therefore, it is neither the purpose nor intent of our textbook to serve as an authoritative source on any medical condition, treatment plan, or clinical intervention, nor should our textbook be used to rigorously define a standard of care that should be practiced by all clinicians.

Our written word provides the physician with a literature-referenced database and a reasonable clinical guide combined with practical suggestions from individual experienced practitioners. We offer a general reference source and clinical road map on a variety of conditions and procedures that may confront emergency clinicians who are experienced in emergency medicine practice. This text cannot replace physician judgment, cannot describe every possible aberration, nuance, clinical scenario, or presentation, and cannot define rigid standards for clinical actions or procedures. Every medical encounter must be individualized, and every patient must be approached on a case-by-case basis. No complex medical interaction can possibly be reduced to the written word. The treatments, procedures, and medical conditions described in this text do not constitute the total expertise or knowledge base expected to be possessed by all emergency clinicians. Finally, many of the described complications and adverse outcomes associated with implementing or withholding complex medical and surgical interventions may occur, even when every aspect of the intervention has been standard or performed correctly.

The editors and authors of Rosen’s Emergency Medicine: Concepts and Clinical Practice, Ninth Edition
Airway

Calvin A. Brown III | Ron M. Walls

SECTION ONE 
Critical Management Principles

CHAPTER 1
Airway

PRINCIPLES

Background

Airway management is the cornerstone of resuscitation and is a defining skill for the specialty of emergency medicine. The emergency clinician has primary airway management responsibility, and all airway techniques lie within the domain of emergency medicine. Although rapid sequence intubation (RSI) is the most commonly used method for emergent tracheal intubation, emergency airway management includes various intubation techniques and devices, approaches to the difficult airway, and rescue techniques when intubation fails.

Anatomy, Physiology, and Pathophysiology

The decision to intubate should be based on careful patient assessment and appraisal of the clinical presentation with respect to three essential criteria: (1) failure to maintain or protect the airway; (2) failure of ventilation or oxygenation; and (3) the patient’s anticipated clinical course and likelihood of deterioration.

Failure to Maintain or Protect the Airway

A patent airway is essential for adequate ventilation and oxygenation. If a patient is unable to maintain a patent airway, the airway should be established by using airway maneuvers such as repositioning, chin lift, jaw thrust, or insertion of an oral or nasal airway. Likewise, the patient must be able to protect against the aspiration of gastric contents, which carries significant morbidity and mortality. Historically, the presence of a gag reflex has been advocated as a reliable indicator of the patient’s ability to protect the airway, but this has been definitively proven to be unreliable because the gag reflex is present in 12% to 25% of normal adults, and there is no evidence that its presence or absence corresponds to airway protective reflexes or predicts the need for intubation. The patient’s ability to swallow or handle secretions is a more reliable indicator of airway protection. The recommended approach is to evaluate the patient’s level of consciousness, ability to phonate in response to voice command or query, which provides information about the integrity of the upper airway and level of consciousness, and ability to manage his or her own secretions (eg, pooling of secretions in the oropharynx, absence of swallowing spontaneously or on command). In general, a patient who requires a maneuver to establish a patent airway or who easily tolerates an oral airway requires intubation for airway protection, unless there is a temporary or readily reversible condition, such as an opioid overdose.

Failure of Ventilation or Oxygenation

Gas exchange, both oxygenation and removal of carbon dioxide, is required for vital organ function. Ventilatory failure that is not reversible by clinical means or persistent hypoxemia despite maximal oxygen supplementation is a primary indication for intubation. This assessment is clinical and includes an evaluation of the patient’s general status, oxygen saturation by pulse oximetry, and ventilatory pattern. Continuous capnography also can be helpful but is not essential if oximetry readings are reliable. Arterial blood gases (ABGs) generally are not required to determine the patient’s need for intubation. In most cases, clinical assessment, including pulse oximetry with or without capnography, and observation of improvement or deterioration in the patient’s clinical condition lead to a correct decision. ABG results are rarely helpful, are time-consuming to obtain, and may be misleading, causing a false sense of security and delay in intubating a deteriorating patient. If obtained, they should be interpreted carefully in the context of the patient’s clinical status. Patients who are clinically improving despite severe or apparently worsening ABG alterations may not require intubation, whereas a rapidly tiring asthmatic may require intubation, even though ABG values are only modestly disturbed.

The need for prolonged mechanical ventilation generally mandates intubation. An external mask device, continuous positive airway pressure (CPAP) and bi-level positive airway pressure (BL-PAP), have all been used successfully to manage patients with exacerbations of chronic obstructive pulmonary disease (COPD) and congestive heart failure, obviating the need for intubation (see Chapter 2) but, despite these advances, many patients who need assisted ventilation or positive pressure to improve oxygenation require intubation.1,2

Anticipated Clinical Course

Certain conditions indicate the need for intubation, even without an immediate threat to airway patency or adequacy of ventilation and oxygenation. These conditions are characterized by a moderate to high likelihood of predictable airway deterioration or the need for intubation to facilitate a patient’s evaluation and treatment. Intubation may be indicated relatively early in the course of certain overdoses. Although the patient initially may be protecting the airway and exchanging gas adequately, intubation is advisable to guard against the strong likelihood of clinical deterioration, which can occur after the initial phase of care when the patient is no longer closely observed. A patient who has sustained significant multiple traumatic injuries may require intubation, even if the patient is ventilating normally through a patent airway and has adequate oxygen levels. For example, a multiple trauma
patient with hypotension, open femur fracture, and diffuse abdominal tenderness warrants early intubation, even if the patient is initially awake and alert, without airway injury or hypoxemia. Active resuscitation, pain control, need for invasive procedures and imaging outside of the emergency department (ED), and inevitable operative management dictate the need for early airway control. In addition, a patient with penetrating neck trauma may have a patent airway and adequate gas exchange. Nevertheless, early intubation is advisable when there is evidence of vascular or direct airway injury because these patients tend to deteriorate, and increasing hemorrhage or swelling in the neck will compromise the airway and confound later attempts at intubation.

The common thread among these indications for intubation is the anticipated clinical course. In each case, it can be anticipated that future events may compromise the patient’s ability to maintain and protect the airway or ability to oxygenate and ventilate, and waiting until these occur may result in a difficult airway.

Identification of the Difficult Airway

In most patients, intubation is technically easy and straightforward. Although early ED-based observational registries reported cricothyrotomy rates of about 1% for all intubations, more recent studies have shown a lower rate, less than 0.5%. As would be expected with an unselected, unscheduled patient population, the ED cricothyrotomy rate is greater than in the operating room, unexpected with an unselected, unscheduled patient population, the airway characteristics is highly predictive of a challenging intubation and difficult BMV, placement of and ventilation with an extraglottic device (EGD; see later discussion), potential difficult intubation and difficult BMV, placement of and ventilation with an extraglottic device (EGD; see later discussion), and cricothyrotomy. Knowledge of all four domains is crucial to successful planning. A patient who exhibits obvious difficult airway characteristics is highly predictive of a challenging intubation, although the emergency clinician should always be ready for a difficult to manage airway, because some difficult airways may not be identified by a bedside assessment.

Airway difficulty exists on a spectrum and is contextual to the provider’s experience, environment, and armamentarium of devices. Airways predicted to be difficult when using a traditional laryngoscope may not prove to be difficult when a videolaryngoscope is used. Some patients may have a single minor anatomic or pathophysiologic reason for airway difficulty, whereas others may have numerous difficult airway characteristics. Although both sets of patients represent potential intubation challenges, the latter group would likely have crossed a threshold beyond which neuromuscular blockade would be avoided because a so-called can’t intubate and can’t oxygenate failed airway may ensue. In these cases, a preferred approach would include topical anesthesia, parenteral sedation, and intubation without the use of a neuromuscular blocking agent (NBMA). Occasionally, RSI remains the preferred method, despite a concerning bedside assessment, when it is part of a planned approach to the difficult airway. This may include use of a double setup, in which a rescue approach, such as cricothyrotomy, is simultaneously prepared in the event of intubation failure. Regardless of the results of a reassuring bedside assessment for airway difficulty, significant challenges may be encountered with intubation and bag mask ventilation and the clinician must be prepared for unanticipated difficulty.

Difficult Direct Laryngoscopy: LEMON

Glottic visualization is paramount in emergency airway management. With direct laryngoscopy (DL), if the vocal cords can be seen (Cormack and Lehane [CL] grade I or II view; Fig. 1.1), the chance of intubation success is high. However, when the glottic aperture cannot be visualized (CL grade III or IV), intubation success is less likely. Very few of the difficult airway markers thought to limit DL access have been scientifically validated, yet applying them in combination can provide a reasonable assessment of anticipated airway difficulty. Videolaryngoscopy, on the other hand, rarely fails to provide adequate laryngeal visualization, so characterization of difficult videolaryngoscopy predictors may not be possible. Like DL, adequate video views are highly correlated with intubation success, although the strength of this association can depend on the device used and operator experience. Whether DL or videolaryngoscopy is planned, a standard screening process for difficulty should be undertaken with every patient. Our recommended approach uses the mnemonic LEMON (Box 1.1).

Look externally for signs of difficult intubation (by gestalt)

III predicts moderate difficulty, and class IV predicts a high degree of difficulty. A meta-analysis has confirmed that the four-class Mallampati score performs well as a predictor of difficult laryngoscopy (and, less so, of difficult intubation), but the Mallampati score alone is not a sufficient assessment tool. A Mallampati score necessitates an awake compliant patient to perform the assessment in the way in which it was originally described. Nearly 50% based simply on the intubator’s clinical impression or initial gestalt. For example, the severely bruised and bloodied face of a combative trauma patient, immobilized in a cervical collar on a spine board, should (correctly) invoke an immediate appreciation of anticipated difficult intubation. Subjective clinical judgment can be highly specific but insensitive and so should be augmented by other evaluations whether or not the airway appears to be challenging.

E—Evaluate 3-3-2. The second step in the evaluation of the difficult airway is to assess the patient’s airway geometry to determine suitability for DL. Glottic visualization with a direct laryngoscope necessitates that the mouth opens adequately, the submandibular space is adequate to accommodate the tongue, and the larynx be positioned low enough in the neck to be accessible. These relationships have been explored in various studies by external measurements of mouth opening, oropharyngeal size, neck movement, and thyromental distance. The 3-3-2 rule is an effective summary of these assessments. The 3-3-2 rule requires that the patient be able to place three of his or her own fingers between the open incisors, three of his or her own fingers along the floor of the mouth, beginning at the mentum, and two fingers from the laryngeal prominence to the underside of the chin (Fig. 1.2). A patient with a receding mandible and high-riding larynx is impossible to intube using DL because the operator cannot adequately displace the tongue and overcome the acute angle for a direct view of the glottic aperture. In practice, the operator compares the size of his or her fingers with the size of the patient’s fingers and then performs the three tests.

M—Mallampati Scale. Oral access is assessed with the Mallampati scale (Fig. 1.3). Visibility of the oral pharynx ranges from complete visualization, including the tonsillar pillars (class I), to no visualization at all, with the tongue pressed against the hard palate (class IV). Classes I and II predict adequate oral access, class III predicts moderate difficulty, and class IV predicts a high degree of difficulty. A meta-analysis has confirmed that the four-class Mallampati score performs well as a predictor of difficult laryngoscopy (and, less so, of difficult intubation), but the Mallampati score alone is not a sufficient assessment tool. A Mallampati score necessitates an awake compliant patient to perform the assessment in the way in which it was originally described. Nearly 50%
of ED patients cannot willingly perform this assessment, but it can be improvised by using a direct laryngoscope blade as a tongue depressor in obtunded or uncooperative patients.7

**O—Obstruction or Obesity.** Upper airway (supraglottic) obstruction may make visualization of the glottis, or intubation itself, mechanically impossible. Conditions such as epiglottitis, head and neck cancer, Ludwig’s angina, neck hematoma, glottis swelling, or glottic polyps can compromise laryngoscopy, passage of the endotracheal tube (ETT), BMV, or all three. Examine the patient for airway obstruction and assess the patient’s voice to satisfy this evaluation step. Although obesity alone may not be an independent marker of difficult direct laryngoscopy, it likely contributes to challenges in other areas of airway management. Nevertheless, obese patients generally are more difficult to intubate than their nonobese counterparts, and preparations should account for this and for the more rapid oxyhemoglobin desaturation and increased difficulty with ventilation using BMV or an EGD (see later).

**N—Neck Mobility.** Neck mobility is desirable for any intubation technique and is essential for positioning the patient for optimal DL. Neck mobility is assessed by flexion and extension of the patient’s head and neck through a full range of motion. Neck extension is the most important motion, but placing the patient in the full sniffing position provides the optimal laryngeal view by DL.10 Modest limitations of motion do not seriously impair DL, but severe loss of motion, as can occur in anklyosing spondylitis or rheumatoid arthritis, for example, may make DL impossible. Cervical spine immobilization in trauma patients artificially reduces cervical spine mobility, but DL is still highly successful in this group of patients.7

A similar mnemonic, LEMONS, has been described, with the “S” referring to the patient’s oxygen saturation. Although not a direct contributor to difficulty with DL, a low starting oxygen saturation will result in a shorter period of safe apnea and a truncated time to perform laryngoscopy and successful endotracheal tube placement. As noted, identification of a difficult intubation does not preclude use of an RSI technique. The crucial determination is whether the emergency clinician judges that the patient has a reasonable likelihood of intubation success, despite the difficulties identified, and that ventilation with BMV or an EGD will be successful in case intubation fails (hence, the value of the BMV and EGD assessments; see Boxes 1.2 and 1.3).

**Difficult Bag-Mask Ventilation: MOANS**

Attributes of difficult BMV have largely been validated and can be summarized with the mnemonic MOANS (Box 1.2).

- **Mask seal compromise or difficulty**
- **Obstruction (particularly supraglottic obstruction, but can be present anywhere in the airway)** or **Obesity** (because of redundant upper airway tissues, chest wall weight, and resistance of abdominal mass)
- **Advanced Age** (best judged by the physiologic appearance of the patient, but age older than 55 years increases risk)
- **Edentulous patients (“No teeth”), which independently interferes with mask seal**
- **Stiffness or resistance to ventilation** (eg, asthma, COPD, pulmonary edema, restrictive lung disease, term pregnancy)—may contribute to increased difficulty with BMV

The difficulty with BMV of the edentulous patient is the basis of the advice often cited for patients with dentures: “teeth out to intubate, teeth in to ventilate.” Another approach involves placing the mask inside the patient’s lower lip. This may limit air leak in patients without teeth and eliminates the risk of aspiration associated with dental prosthetics or rolled gauze (Fig. 1.4).11 Difficult BMV is not uncommon but, with proper technique, it usually is successful. A review by Kheterpal et al of more than 50,000 patients undergoing elective anesthesia has found that impossible BMV is exceptionally rare (0.2%) and is associated with neck changes secondary to radiation therapy, presence of a beard, male gender, history of sleep apnea, and Mallampati class III or IV airway.12 Impossible BMV was five times more likely if one of these factors was present and 25 times more likely with four or more.

**Difficult Extraglottic Device Placement: RODS**

Placement of an EGD, such as a laryngeal mask airway (LMA), Combitube, or similar upper airway device, often can convert a can’t intubate, can’t oxygenate situation to a can’t intubate, can oxygenate situation, which allows time for rescue of a failed airway (see following section). Difficulty achieving placement or ventilation with an EGD can be predicted by the mnemonic RODS. Fortunately, if the emergency clinician has already performed the LEMON and MOANS assessments, only the D for distorted anatomy remains to be evaluated (Box 1.3). EGDs are placed blindly and have a mask or balloon structure that, when inflated, obstructs the oropharynx proximally and esophageal inlet distally, permitting indirect ventilation. Distorted upper airway anatomy can result in a poor seal and ineffective ventilation.

**Difficult Cricothyrotomy: SMART**

Difficult cricothyrotomy can be anticipated whenever there is limited access to the anterior neck or obscured laryngeal

- **Stiffness (resistance to ventilation)**

landmarks and can be remembered by the mnemonic SMART (Box 1.4). Prior surgery, hemotoma, tumor, abscess, scarring (as from radiation therapy or prior injury), local trauma, obesity, edema, or subcutaneous air each has the potential to make cricothyrotomy more difficult. Perform an examination for the landmarks needed to perform cricothyrotomy as part of the pre-intubation difficult airway assessment of the patient. Point-of-care ultrasound has been used at the bedside to locate the cricothyroid membrane, thereby allowing the emergency clinician to mark the location on the surface of the neck in high-risk cases. The emergency clinician should not avoid performing a rescue cricothyrotomy when indicated, even in the presence of predicted difficulty.

**Measurement and Incidence of Intubation Difficulty**

The actual degree to which an intubation is difficult is highly subjective, and quantification is challenging. The CL system is the most widely used system for grading a laryngoscopic view of the glottis, which grades laryngoscopy according to the extent to which laryngeal and glottic structures can be seen (see Fig. 1.1). In grade 1 laryngoscopy, all or nearly all of the glottic aperture is seen; in grade 2, the laryngoscopist visualizes only a portion of the glottis (arytenoid cartilages alone or arytenoid cartilages plus part of the vocal cords), in grade 3 only the epiglottis is visualized and, in grade 4, not even the epiglottis is visible.

Fewer than 1% of stable patients undergoing DL during elective anesthesia yield a grade 4 laryngoscopy, a finding associated with an extremely difficult intubation with. Grade 3 laryngoscopy, which represents highly difficult intubation, is found in less than 5% of patients. Grade 2 laryngoscopy, which occurs in 10% to 30% of patients, can be subdivided further into grade 2a, in which the arytenoids and a portion of the vocal cords are seen, and grade 2b, in which only the arytenoids are seen. Intubation failure occurs in 67% of grade 2b cases but in only 4% of grade 2a cases.

Outside of the operating room, the rate of difficulty may be higher. In a recent review of emergency adult inpatient intubations, as many as 10% were considered difficult (grade 3 or 4 CL direct view or more than three attempts required).12 The incidence of difficult ED intubations is unknown but is likely much higher. Approximately 80% of all grade 2 laryngoscopies are grade 2a; the rest are grade 2b. First-attempt intubation success drops off significantly as the glottic view transitions from a grade 2a to 2b; however, a grade 1 view is associated with virtually 100% intubation success. An alternative system, POGO (percentage of glottic opening), also has been proposed and validated but has not been widely used or studied. The incidence of difficult intubation, and the predictors thereof, are largely based on the use of conventional DL and are not applicable to videolaryngoscopy.

**Confirmation of Endotracheal Tube Placement**

Immediately after intubation, the intubator should apply an end-tidal carbon dioxide (ETCO₂) detection device to the ETT and assess it through six manual ventilations. Disposable colorimetric ETCO₂ detectors are highly reliable, convenient, and easy to interpret, indicating adequate CO₂ detection by color change (Figs. 1.5 and 1.6) and determining tracheal and esophageal intubation in patients with spontaneous circulation. The persistence of detected CO₂ after six manual breaths indicates that the tube is within the airway, although not necessarily within the trachea. CO₂ is detected with the tube in the mainstem bronchus, trachea, or supraglottic
space. Correlation of \(^{\text{ETC}}_{\text{O}}\) detection with the depth markings on the ETT, particularly important in pediatric patients, confirms tracheal placement. Rarely, BMV before intubation or ingestion of carbonated beverages may lead to the release of \(^{\text{CO}_2}\) from the stomach after esophageal intubation, causing a transient false indication of tracheal intubation. Washout of this phenomenon universally occurs within six breaths.

Although colorimetric \(^{\text{ETC}}_{\text{O}}\) measurement is highly sensitive and specific for detecting esophageal intubation, caution is required for patients in cardiopulmonary arrest. Insufficient gas exchange may prevent \(^{\text{CO}_2}\) detection in the exhaled air, even when the tube is correctly placed within the trachea. In patients in cardiopulmonary arrest, a \(^{\text{CO}_2}\) level greater than 2%, which is the threshold for color change on colorimetric capnometers, should be considered definitive evidence of correct ETT placement, but the absence of such \(^{\text{CO}_2}\) cannot be used reliably as an indicator of esophageal intubation. Recent resuscitation guidelines have suggested continuous quantitative measurement of \(^{\text{ETC}}_{\text{O}}\) during cardiac arrest to gauge the efficacy of cardiopulmonary resuscitation. This circumstance arises in approximately 25% to 40% of intubated cardiac arrest patients. In all other patients, absence of \(^{\text{CO}_2}\) detection indicates failure to intubate the trachea, and rapid reintubation is indicated.

When \(^{\text{ETC}}_{\text{O}}\) detection is not possible, tracheal tube position can be confirmed with other techniques. One approach involves point-of-care ultrasound. In live patient and cadaver studies, ultrasonography performed over the cricothyroid membrane or upper trachea has accurately confirmed ETT position in the trachea, especially during intubation.

Another method of tube placement confirmation is the aspiration technique, based on the anatomic differences between the trachea and esophagus. The esophagus is a muscular structure with no support within its walls and is therefore collapsible when negative pressure is applied. The trachea is held patent by cartilaginous rings and thus is less likely to collapse when negative pressure is applied. Vigorous aspiration of air through the ETT with the ETT cuff deflated results in occlusion of the ETT orifices by the soft walls of the esophagus, whereas aspiration after tracheal placement of the tube is easy and rapid.

Bulb or syringe aspiration devices may be used in patients in cardiac arrest who have no detectable \(^{\text{CO}_2}\). Although such devices are highly reliable at detecting esophageal intubation (sensitivity > 95%), false-positives, in which a correctly placed tracheal tube is incorrectly identified as esophageal, can occur in up to 25% of cardiac arrest patients. Aspiration devices may be useful in the out-of-hospital setting when poor lighting hampers colorimetric \(^{\text{ETC}}_{\text{O}}\) determination. They also are good backup devices when cardiac arrest confounds attempts to assess placement with \(^{\text{ETC}}_{\text{O}}\). Detection of expired \(^{\text{CO}_2}\) is more reliable and is the standard for confirmation of tracheal placement of an ETT and for early detection of accidental esophageal intubation. Aspiration devices have a valuable but secondary role. Also, a bougie can be placed through the center of an ETT to corroborate tube location further. A bougie that can be passed deeply through the tube, with little or no resistance, suggests an esophageal intubation because the bougie has likely passed beyond the tube and into the stomach. If the ETT is in the trachea, the tip of the bougie will become wedged after only a few inches, likely in the right mainstem bronchus, and a vibration from contact with the anterior tracheal rings may be transmitted to the operator’s fingertips.

Accordingly, \(^{\text{ETC}}_{\text{O}}\) detection, with aspiration, bougie, or an ultrasound technique as backup, should be considered the primary means of ETT placement confirmation. Secondary means include physical examination findings, oximetry, and radiography. The examiner should auscultate both lung fields and the epigastric area. Pulse oximetry is indicated as a monitoring technique in all critically ill patients, not just those who require intubation. Oximetry is useful in detecting esophageal intubation but may not show a decreasing oxygen saturation for several minutes after a failed intubation because of the oxygen reservoir (preoxygenation) created in the patient before intubation. Although chest radiography is universally recommended after ETT placement, its primary purpose is to ensure that the tube is well positioned below the cords and above the carina. A single anteroposterior chest radiograph is not sufficient to detect esophageal intubation, although esophageal intubation may be detected if the ETT is clearly outside the air shadow of the trachea. In cases in which doubt persists, a fiberoptic scope can be passed through the ETT to identify tracheal rings, another gold standard for confirmation of tracheal placement.

**MANAGEMENT**

**Decision Making**

Algorithms for emergency airway management have been developed and provide a useful guide for planning intubation and rescue in case of intubation failure. The algorithm assumes that a decision to intubate has been made and outlines such an approach. The approach is predicated on two key determinations that are to be made before active airway management is initiated (Fig. 1.7). The first determination is whether the patient is in cardiopulmonary arrest or a state of near arrest and is likely to be unresponsive to direct laryngoscopy. Such a patient—agonal, near death, in
circulatory collapse—is deemed a crash airway patient for the purposes of emergency airway management and is treated using the crash airway algorithm by an immediate intubation attempt without use of drugs; this can be supplemented by a single large dose of succinylcholine if the attempt to intubate fails, and the patient is thought not to be sufficiently relaxed (Fig. 1.8). If a crash airway is not present, a decision of whether the patient represents a difficult intubation, as determined by the LEMON, MOANS, RODS, and SMART evaluations is made and, if so, the difficult airway algorithm is used (Fig. 1.9).

For patients who require emergency intubation but who have neither a crash airway nor a difficult airway, RSI is indicated. RSI provides the safest and quickest method of achieving intubation in such patients. After administration of RSI drugs, intubation attempts are repeated until the patient is intubated or a failed intubation is identified. If more than one intubation attempt is required, oxygen saturation is monitored continuously and, if saturation falls to 90% or less, BMV is performed until saturation is recovered for another attempt. If the oxygen saturation continues to fall, despite optimal use of BMV or EGD, a failed airway exists. This is referred to as a can’t intubate, can’t oxygenate scenario. A failed airway also is defined as three unsuccessful attempts at laryngoscopy because subsequent attempts at laryngoscopy by the same clinician are unlikely to succeed. The three failed laryngoscopy attempts are defined as attempts by an experienced clinician using the best possible patient positioning and technique. Three attempts by a physician trainee using a direct laryngoscope may not count, necessarily, as best attempts if an experienced emergency clinician is available or videolaryngoscopy has not yet been attempted. Also, if the emergency clinician ascertains after even a single attempt that intubation will be impossible (eg, grade 4 laryngoscopic view with DL, despite optimal patient positioning and use of external laryngeal manipulation), and no alternative device (eg, videolaryngoscope, intubating LMA) is available, a failed airway is present. The failed airway is managed according to the failed airway algorithm (Fig. 1.10).

Difficult Airway

The perception of a difficult airway is relative, and many emergency intubations could be considered difficult. Deciding whether to treat the airway as a typical emergency airway or whether to use the difficult airway algorithm is based on the degree of perceived difficulty, operator experience, armamentarium of airway devices available, and individual circumstances of the case. The LEMON, MOANS, RODS, and SMART assessments provide a systematic framework to assist in identifying the potentially difficult airway.
When preintubation evaluation identifies a potentially difficult airway (see Fig. 1.9), the approach is based on the premise that NMBAs generally should not be used unless the emergency clinician believes that (1) intubation is likely to be successful and (2) oxygenation can be maintained via BMV or EGD should the patient desaturate during a failed intubation attempt. The one exception to this recommendation occurs in the forced to act scenario. A forced to act imperative permits RSI, even in a highly difficult airway situation in which the operator is not confident of the success of laryngoscopy or of sustaining oxygenation. This usually occurs in the setting of a rapidly deteriorating patient with an obviously difficult airway and a presumed clinical trajectory of imminent arrest. Although this is not yet a crash airway situation, the operator is forced to act—that is, there is a need to act immediately to intubate before orotracheal intubation quickly becomes impossible or the patient arrests. The patient retains sufficient muscle tone and voluntary effort (including combative behavior induced by hypoxia) to require administration of drugs before intubation can be attempted. Consider an agitated patient with rapidly advancing anaphylaxis or angioedema, a morbidly obese patient in severe, end-stage status asthmaticus, or an intensive care unit (ICU) patient with inadvertent or premature extubation, respiratory failure, and difficult airway. Within seconds to minutes, perhaps before a full difficult airway assessment can be done or preparations can be completed for an alternative airway approach (eg, flexible endoscopy), the patient’s rapid deterioration signals impending respiratory arrest. This is a unique situation in which the operator may be compelled to take the one best chance to secure the airway by rapidly administering RSI drugs, despite obvious airway difficulty, and attempting intubation before the airway crisis has advanced to the point that intubation is impossible or delay has caused hypoxic arrest. If laryngoscopy fails, the RSI drugs have optimized patient conditions for cricothyrotomy or insertion of an alternative airway device, depending on the operator’s judgment.

Therefore, in the difficult airway algorithm, the first determination is whether the operator is forced to act. If so, RSI drugs are given, a best attempt at laryngoscopy is undertaken and, if intubation is not successful, the airway is considered failed, and the operator moves immediately to the failed airway algorithm. In the vast majority of difficult airway situations, however, the operator is not forced to act, and the first step is to ensure that oxygenation is sufficient to permit a planned orderly approach to airway management. If oxygenation is inadequate and cannot be made adequate by supplementation with BMV, the airway should be considered a failed airway. Although inadequate oxygenation should be defined on a case by case basis, oxygenation saturation falling below 90% is the accepted threshold, because this represents the point at which hemoglobin undergoes a conformational change, more readily releases oxygen, and increases the pace of further desaturation. Oxyhemoglobin saturations in the mid-80s, if holding steady, might be considered adequate in some circumstances, particularly if the patient is chronically hypoxemic. When oxygenation is inadequate or dropping, the failed airway algorithm should be used because the predicted high degree of intubation difficulty, combined with failure to maintain oxygen saturation, is analogous to the can’t intubate, can’t oxygenate scenario.

When oxygenation is adequate, however, the next consideration is whether RSI is appropriate, on the basis of the operator’s assessment of the likelihood of (1) successful ventilation with BMV or EGD in case intubation is unsuccessful and (2) the likelihood of successful intubation by laryngoscopy. If the operator judges laryngoscopy likely to succeed and is confident that he or she can oxygenate the patient if intubation fails, RSI is performed. In such cases, a double setup can be used in which RSI is planned and preparations are simultaneously undertaken for rescue cricothyrotomy or another rescue technique. If the operator is not confident of successful intubation by RSI and time allows, an awake technique can be used. In this context, awake means that the patient continues to breathe and, although intravenous sedation and analgesia may be administered, can cooperate with caregivers. The patient is prepared by applying topical anesthesia with atomized or nebulized lidocaine, ideally preceded by a drying agent such as glycopyrrolate. Titrated doses of a sedative and analgesic agents (or ketamine, which provides both actions) may be required for the patient to tolerate the procedure. Once this is accomplished, a number of different devices can then be used to attempt glottic visualization, although flexible bronchoscopes and videolaryngoscopes are preferable. If the glottis is adequately visualized, the patient can be intubated at that time or, in a stable difficult airway situation, the emergency clinician may proceed with planned RSI, now assured of intubation success. If the awake laryngoscopy is unsuccessful, the patient can be intubated with any of numerous techniques shown in the last box in Fig. 1.9. For each of these methods, the patient is kept breathing but is variably sedated and anesthetized. The choice among these methods depends on clinician experience and preference, device availability, and patient attributes.

**Failed Airway**

Management of the failed airway is dictated by whether the patient can be oxygenated. If adequate oxygenation cannot be maintained with rescue BMV, the rescue technique of first resort is cricothyrotomy (see Fig. 1.10). Multiple attempts at other methods in the context of failed oxygenation only delay cricothyrotomy and place the patient at increased risk for hypoxic brain injury. If an alternative device (ie, an EGD such as an LMA or Combitube) is readily available, however, and the operator judges it to be an appropriate device for the patient’s anatomy, single attempt can
be made to use it simultaneously with preparations for immediate cricothyrotomy as long as initiation of cricothyrotomy is not delayed. If early indications are that an EGD is effective and oxygenation improves, cricothyrotomy can wait; however, the operator must constantly reassess EGD function and oxygenation status. If the EGD subsequently fails, cricothyrotomy must begin without delay.

If adequate oxygenation is possible, several options are available for the failed airway. In almost all cases, cricothyrotomy is the definitive rescue technique for the failed airway if time does not allow for other approaches (ie, preservation of oxygenation) or if they fail. The fundamental difference in philosophy between the difficult and failed airway is that the difficult airway is planned for, and the standard is to place a definitive airway (cuffed ETT) in the trachea. The failed airway is not planned for, and the standard is to achieve an airway that provides adequate oxygenation to avert hypoxic brain injury. Some devices used in the failed airway (eg, EGDs) are temporary and do not provide definitive airway protection.

Methods of Intubation

Although many techniques are available for intubation of the emergency patient, four methods are the most common, with RSI being the most frequent approach.

Rapid Sequence Intubation

RSI is the cornerstone of modern emergency airway management and is defined as the nearly simultaneous administration of a potent sedative (induction) agent and NMBa, usually succinylcholine or rocuronium, for the purpose of tracheal intubation. This approach provides optimal intubating conditions and has long been thought to minimize the risk of aspiration of gastric contents. A systematic review of the literature in 2007 failed to prove that RSI results in a lower incidence of aspiration than other techniques, but the authors correctly noted that virtually no studies have ever been designed to measure this precise endpoint. RSI is nevertheless the most widely used technique for emergency intubation of patients without identifiable difficult airway attributes, with recent large registry data showing that it is used in 85% of all emergency department intubations. The central concept of RSI is to take the patient from the starting point (eg, conscious, breathing spontaneously) to a state of unconsciousness with complete neuromuscular paralysis, and then to achieve intubation without interposed assisted ventilation. The risk of aspiration of gastric contents is thought to be significantly higher for patients who have not fasted before induction. Application of positive-pressure ventilation can cause air to pass into the stomach, resulting in gastric distention and likely increasing the risk of regurgitation and aspiration. The purpose of RSI is to avoid positive-pressure ventilation until the ETT is placed correctly in the trachea, with the cuff inflated. This requires a preoxygenation phase, during which mixed alveolar gases (mostly nitrogen) within the lungs’ functional residual capacity are replaced with oxygen, permitting at least several minutes of apnea (see later discussion) in a healthy normal body habitus adult before oxygen desaturation to less than 90% ensues (Fig. 1.11).

Use of RSI also facilitates successful endotracheal intubation by causing complete relaxation of the patient’s musculature, allowing better access to the airway. Finally, RSI permits pharmacologic control of the physiologic responses to laryngoscopy and intubation, mitigating potential adverse effects. These effects include further elevations in intracranial pressure (ICP) in response to the procedure and to the sympathetic discharge resulting from laryngoscopy (Box 1.5). RSI is a series of discrete steps, and every step should be planned (Box 1.6).

**BOX 1.5**

**Pretreatment Agents for Rapid Sequence Intubation**

*Reactive airway disease: Albuterol, 2.5 mg, by nebulizer. If time does not permit albuterol nebulizer, give lidocaine 1.5 mg/kg IV.

*Cardiovascular disease: Fentanyl, 3 µg/kg, to mitigate sympathetic discharge

*Elevated ICP: Fentanyl, 3 µg/kg, to mitigate sympathetic discharge and attendant rise in ICP

**BOX 1.6**

**The Seven Ps of Rapid Sequence Intubation**

1. Preparation
2. Preoxygenation
3. Pretreatment
4. Paralysis with induction
5. Positioning
6. Placement of tube
7. Postintubation management

**Preparation.** In the initial phase, the patient is assessed for intubation difficulty, unless this has already been done, and the intubation is planned, including determining dosages and sequence of drugs, tube size, and laryngoscope type, blade, and size. Drugs are drawn up and labeled. All necessary equipment is
Preoxygenation. Administration of 100% oxygen for 3 minutes of normal tidal volume breathing in a normal healthy adult establishes an adequate oxygen reservoir to permit 6 to 8 minutes of safe apnea before oxygen desaturation to less than 90% occurs (see Fig. 1.11). Additional preoxygenation does not improve arterial oxygen tension. The time to desaturation to less than 90% in children, obese adults, late-term pregnant women, and patients who are acutely ill or injured is considerably shorter. Desaturation time also is reduced if the patient does not inspire 100% oxygen. Nevertheless, adequate preoxygenation usually can be obtained, even in ED patients, to permit minutes of apnea before there is oxygen desaturation to less than 90%. Preoxygenation is also essential to the no-bagging approach of RSI. If time is insufficient for a full 3-minute preoxygenation phase, eight vital capacity breaths with high-flow oxygen can achieve oxygen saturations and apnea times that match or exceed those obtained with traditional preoxygenation. Desaturation time in obese patients can be prolonged by preoxygenating with the patient in a head-up position and by continuing supplemental oxygen (via nasal cannula at a flow rate of 5–15 L/min) after motor paralysis and during laryngoscopy until the ETT is successfully placed. In obese patients, it extends the time to desaturation to 95% from 3.5 to 5.3 minutes. This so-called apneic oxygenation takes advantage of a physiologic principle termed *ventilatory mass flow*. Even though patients are paralyzed during RSI, circulation is unaltered. The constant diffusion of alveolar oxygen into the pulmonary circulation creates a natural downward gradient promoting passive oxygen movement from the patient’s upper airway into the gas-exchanging portions of the lungs. Oxygen saturation monitors permit earlier detection of desaturation during laryngoscopy, but preoxygenation remains an essential step in RSI.

Pretreatment. During this phase, drugs are administered 3 minutes before the administration of succinylcholine and an induction agent to mitigate the adverse physiologic effects of laryngoscopy and intubation on the patient’s presenting condition. Pretreatment approaches have evolved over time. Periodic reappraisals of the available literature have whittled the pretreatment approach down to the bare essentials with a focus on optimizing patient physiology prior to any intubation attempts. Older practices, such as the routine use of atropine for intubation of small children, have largely been abandoned.

Intubation is intensely stimulating and results in a sympathetic discharge, or reflex sympathetic response to laryngoscopy (RSRL). In patients suffering from a hypertensive emergency, sympatholyis with fentanyl (3 mcg/kg IV) administered 3 minutes before RSI can optimize the patient’s hemodynamics by attenuating spikes in blood pressure and shear forces, both of which are considered undesirable in patients with elevations of intracranial pressure (ICP), aortic disease, acute coronary syndromes and neurovascular emergencies.

Patients with reactive airways disease can exhibit worsening pulmonary mechanics after intubation as a result of bronchospasm. Controversy exists regarding whether lidocaine (1.5 mg/kg IV) confers any additional benefit, beyond albuterol, and should be considered optional at best. Asthmatic patients being intubated in the ED for status asthmaticus will have received albuterol before intubation, and it is unlikely in these patients that lidocaine has any additive protective effect and is not recommended. Lidocaine has a vanishing role in emergency airway management and may disappear completely in the near future (see Box 1.5).

Paralysis With Induction. In this phase, a potent sedative agent is administered by rapid intravenous (IV) push in a dose capable of producing unconsciousness rapidly. This is immediately followed by rapid administration of an intubating dose of an NMBA, either succinylcholine at a dose of 1.5 mg/kg IV or rocuronium, 1 mg/kg. It is usual to wait 45 seconds from when the succinylcholine is given and 60 seconds from when rocuronium is given to allow sufficient paralysis to occur. The results from two large meta-analyses have revealed that intubating conditions provided by each drug are equivalent as long as rocuronium is dosed between 1.0 and 1.2 mg/kg IV.

Positioning. The patient should be positioned for intubation as consciousness is lost. Usually, positioning involves head extension, often with flexion of the neck on the body. Although simple extension may be adequate, a full sniffing position with cervical spine extension and head elevation is optimal if DL is used. The Sellick maneuver—application of firm, backward pressure over the cricoid cartilage with the goal of obstructing the cervical esophagus and reducing the risk of aspiration—had long been recommended to minimize the risk of passive regurgitation and hence aspiration, but is no longer recommended. The Sellick maneuver is incorrectly applied by a variety of operators, making laryngoscopy or intubation more difficult in some patients, and aspiration often occurs despite use of the Sellick maneuver. In many patients, the cervical esophagus is positioned lateral to the cricoid ring in a relationship that is exaggerated by posterior pressure, rarely resulting in esophageal obstruction. Accordingly, we do not recommend routine use of the Sellick maneuver, and it should be considered optional, applied selectively, and released or modified early if the laryngeal view is poor or tube passage is difficult. After administration of an induction agent and NMBA, although the patient becomes unconscious and apneic, BMV should not be initiated unless the oxygen saturation falls to 90%.

Placement of Tube. Approximately 45 to 60 seconds after administration of the NMBA, the patient is relaxed sufficiently to permit laryngoscopy. This is assessed most easily by moving the mandible to test for mobility and absence of muscle tone. Place the ET during glottic visualization with the laryngoscope. Confirm placement, as described earlier. If the first attempt is unsuccessful but oxygen saturation remains high, it is not necessary to ventilate the patient with a bag and mask between intubation attempts. If the oxygen saturation is approaching 90%, the patient may be ventilated briefly with a bag and mask between attempts to reestablish the oxygen reservoir.

Postintubation Management. After confirmation of tube placement by $\text{ETCO}_2$, obtain a chest radiograph to confirm that mainstem intubation has not occurred and to assess the lungs. If available, place the patient on continuous capnography. In general, long-acting NMAs (eg, pancuronium, vecuronium) are avoided; the focus is on optimal management using opioid analgesics and sedative agents to facilitate mechanical ventilation. An adequate dose of a benzodiazepine (eg, midazolam, 0.1–0.2 mg/kg IV) and opioid analgesic (eg, fentanyl, 3–5 mcg/kg IV, or morphine, 0.2–0.3 mg/kg IV) is given to improve patient comfort and decrease sympathetic response to the ETT. Propofol infusion (5–50 mcg/kg/min IV) with supplemental analgesia is an effective method for managing intubated patients who do not have hypertension or ongoing bleeding and is especially helpful for management of neurologic emergencies because its clinical duration of action is very short (<5 minutes), allowing frequent neurologic examinations. An NMBA is added only if appropriate use of
Preoxygenation—100% oxygen for 3 min or 8 vital capacity breaths

Pretreatment—as indicated

Paralysis with induction
  • Etomidate, 0.3 mg/kg
  • Succinylcholine, 1.5 mg/kg

Positioning—as indicated

Placement
  • Laryngoscopy and intubation
  • End-tidal carbon dioxide confirmation

Postintubation management
  • Sedation and analgesia as indicated
  • Initiate mechanical ventilation
  • NMBA only if needed after adequate sedation and analgesia

Delayed Sequence Intubation

Delayed sequence intubation (DSI) is a new technique proposed to maximize preoxygenation in preparation for intubation. Agitation, delirium, and confusion can make attempts at preoxygenation challenging, if not impossible, when a patient is unable to comply with conventional modes of supplemental oxygenation, such as a face mask or BL-PAP. DSI considers preoxygenation a procedural and uses dissociative doses of ketamine (1.0 mg/kg IV) as procedural sedation to accomplish this. A small, ED- and ICU-based multicenter observational study showed post-DSI oxygen saturations significantly higher than pre-DSI levels. Additionally, there were no noted adverse outcomes or desaturations when intubation eventually took place in this limited case series. More investigation is required to determine the possible indications for and safety of DSI when performed in various ED settings.

Blind Nasotracheal Intubation

Historically, blind nasotracheal intubation (BNTI) was used extensively in the ED and out-of-hospital setting, but it has fallen out of favor largely because of the superiority of RSI. Prehospital intubation success between RSI and BNTI favors RSI, and ED studies have shown that RSI is superior.

In the ED, BNTI rarely, if ever, should be used and is reserved for patients in whom the presence of a narrowly defined type of difficult airway makes RSI undesirable or contraindicated, and alternatives (eg, flexible endoscope) are not available. A review of nearly 9000 ED intubations has shown that nasal intubation was used in only 5% of intubations performed from 1997 to 2002. A current registry of more than 17,500 adult ED intubations between 2002 and 2012 has revealed that this is now less than 0.5%.

Awake Oral Intubation

Awake oral intubation is a technique in which sedative and topical anesthetic agents are administered to permit management of a difficult airway without neuromuscular blockade. Sedation and analgesia are achieved in a manner analogous to that for painful procedures in the ED. Topical anesthesia may be achieved by spray, nebulization, or local anesthetic nerve block. Various sedative agents can be used but ketamine, which provides dissociative anesthesia, analgesia, maintenance of protective airway reflexes, and minimal respiratory depression, is often the best choice (see later, “Pharmacologic Agents”). Aliquots of ketamine at a dose of 0.5 mg/kg IV, titrated to the desired level of sedation and procedural tolerance, is an effective method. Dexmedetomidine (Precedex), a centrally acting alpha receptor blocker, has been used successfully, alone or in combination with benzodiazepines, for awake airway evaluations. A typical dose is 1.0 mg/kg IV infused over 5 to 10 minutes. After the patient is sedated, and topical anesthesia has been achieved, gentle direct videolaryngoscopy or flexible endoscopic laryngoscopy is performed to determine whether the glottis is visible and intubation possible. If the glottis is visible, the patient may be intubated during initial laryngoscopy, or the operator, confident that the glottis can be visualized, may opt to perform RSI to benefit from pretreatment, induction, and paralysis, as might be the case in a head-injured patient.

Awake oral intubation is distinct from the practice of oral intubation with a sedative or opioid agent to obtund the patient for intubation without neuromuscular blockade. This latter technique can be referred to as intubation with sedation alone or, paradoxically, nonparalytic RSI. Intubating conditions and first-attempt success achieved even with deep anesthesia are significantly inferior to what is achieved when neuromuscular blockade is used. In general, the technique of administering a potent sedative agent to obtund the patient’s responses and permit intubation in the absence of neuromuscular blockade is ill-advised and inappropriate for endotracheal intubation in the ED, unless performed as part of an awake intubation (see earlier), during which lesser amounts of sedation are typically used.

Oral Intubation Without Pharmacologic Agents

The arrested or near death patient may not require pharmacologic agents for intubation, but even an arrested patient may retain sufficient muscle tone to render intubation difficult. If the glottis is not adequately visualized, administration of a single dose of succinylcholine alone may facilitate laryngoscopy (see earlier, “Decision Making”). Success rates for intubating unconscious unresponsive patients are variable but approach those achieved with RSI, presumably because the patient is in a similar physiologic state (ie, muscle relaxation, no ability to react to laryngoscopy or tube insertion). This does not apply to patients who are unconscious from neurologic catastrophe or trauma and those who have overdosed or have other medical causes of coma who warrant an induction agent and are intubated with standard RSI procedures (see earlier).

Pharmacologic Agents

Neuromuscular Blocking Agents

motor endplate, causing sustained depolarization of the myocyte while preventing transmembrane potentials from reforming and resisting further stimulation from ACh. The other major class of NMBA comprises the competitive, or nondepolarizing, agents, which bind competitively to ACh receptors, preventing access by ACh and preventing muscular activity. The competitive agents are of two pharmacologically distinct types, steroid-based agents (aminosteroid compounds) and benzylisoquinolines. Each of these basic chemical types has distinct properties, but only aminosteroid compounds are used in the ED.

**Succinylcholine.** Succinylcholine is a combination of two molecules of ACh. Succinylcholine is rapidly hydrolyzed by plasma pseudocholinesterase to succinylmonocholine, which is a weak NMBA, and then to succinic acid and choline, which have no NMBA activity. Pseudocholinesterase is not present at the motor endplate and exerts its effects systemically before the succinylcholine reaches the ACh receptor. Only a small amount of the succinylcholine administered survives to reach the motor endplate. Succinylcholine is active at the motor endplate until it diffuses away. Decreased plasma pseudocholinesterase activity can increase the amount of succinylcholine reaching the motor endplate, prolonging succinylcholine block, but this is of little significance in the emergency setting because the prolongation of action rarely is significant, reaching only 23 minutes at the extreme.

**Uses and Dosing.** Succinylcholine is rapidly active, typically producing intubating conditions within 45 seconds of administration by rapid IV bolus injection. The clinical duration of action before spontaneous respiration is 6 to 10 minutes (see Fig. 1.11). Full recovery of normal neuromuscular function occurs within 15 minutes. The combination of rapid onset, complete reliability, short duration of action, and absence of common serious side effects has kept succinylcholine as the drug of choice for most ED intubations. Time-trended surveillance of ED intubation practices has suggested that succinylcholine is slowly being replaced by rocuronium. The use of a competitive or nondepolarizing NMBA for RSI may be desirable when succinylcholine is contraindicated and in certain other settings. The appropriate dose of succinylcholine for emergency airway management is 1.5 mg/kg IV. Although the effective dose at which paralysis is achieved in 95% of patients (ED95) for succinylcholine paralysis is much lower (0.3 mg/kg), the onset of muscle paralysis is excessively long at these lower doses and is not compatible with emergency intubation. Excellent intubating conditions are best achieved when succinylcholine is contraindicated and in certain other settings. The appropriate dose of succinylcholine for emergency airway management is 1.5 mg/kg IV. Although the effective dose at which paralysis is achieved in 95% of patients (ED95) for succinylcholine paralysis is much lower (0.3 mg/kg), the onset of muscle paralysis is excessively long at these lower doses and is not compatible with emergency intubation. Excellent intubating conditions are best achieved when succinylcholine is dosed at 1.5 mg/kg. Multiple studies have confirmed that the dose of succinylcholine is based on the patient’s total body weight (TBW) and is not adjusted (downward), regardless of the degree of obesity.

**Cardiovascular Effects.** As an ACh analogue, succinylcholine binds to ACh receptors throughout the body, not just at the motor endplate. It is difficult to separate the effects of succinylcholine on the heart caused by direct cardiac muscarinic stimulation from those caused by stimulation of autonomic ganglia by succinylcholine and from the effects induced by autonomic responses to laryngoscopy and intubation. Succinylcholine can be a negative chronotrope, especially in children, and sinus bradycardia may ensue after succinylcholine administration. Sinus bradycardia is treated with atropine, if necessary, but is usually self-limiting. Some pediatric practitioners recommend pretreatment with atropine for children younger than 1 year, but there is no evidence for benefit, and we do not agree with this recommendation. Adults may develop bradycardia after administration of a second dose of succinylcholine. Other cardiac dysrhythmias, including ventricular fibrillation and asystole, have been reported with succinylcholine, but it is impossible to distinguish the effects of the drug itself from those caused by the intense vagal stimulation and catecholamine release that accompany laryngoscopy and intubation. In addition, many of these catastrophic complications occur in critically ill patients, further confounding attempts to identify whether the illness or any particular drug or procedure is the cause.

**Fasciculations.** The depolarizing action of succinylcholine results in fine chaotic contractions of the muscles throughout the body for several seconds during the onset of paralysis in over 90% of patients. Muscle pain occurs in approximately 50% of patients who receive succinylcholine. Although it is has been thought that muscle pains are reduced or abolished by prior administration of a defasciculating dose of a competitive NMBA, the evidence is not conclusive. Use of 1.5 mg/kg of succinylcholine results in less fasciculation and less myalgia than occur with 1 mg/kg.

**Hyperkalemia.** Succinylcholine has been associated with severe fatal hyperkalemia when administered to patients with specific predisposing clinical conditions (Table 1.2). The mechanism whereby severe hyperkalemia occurs is related to receptor upregulation on the postsynaptic muscle membrane. When a muscle is deprived of ACh stimulation for several days, receptor upregulation occurs, causing an increase in receptor density and a change of receptor subtypes on the muscle surface. ACh receptors are primarily K+ ion channels, and at-risk patients can have an immediate massive efflux of potassium as these newly recruited receptors are depolarized by succinylcholine. This occurs predominantly at the site of injury but may also occur in tissue remote from the original insult. Although the hyperkalemia occurs within minutes after administration of succinylcholine and may be severe or fatal, the patient’s vulnerability to succinylcholine-induced hyperkalemia starts as early as 3 days but does not become significant until more than 5 days after the inciting injury or burn, because receptor upregulation production of protein subunits takes time develop.

Succinylcholine remains the agent of choice for RSI in acute burn, trauma, stroke, and spinal cord injury if intubation occurs earlier than 5 days after onset of the condition. If doubt exists regarding the onset time, succinylcholine should be replaced with a competitive NMBA, usually rocuronium. Degenerative neuromuscular disorders, denervation syndromes, or primary myopathies (eg, multiple sclerosis, amyotrophic lateral sclerosis, Duchenne muscular dystrophy) can be particularly troubling, however, because the risk begins the onset of the disease and continues indefinitely, regardless of the apparent stability of the symptoms. In patients with denervation caused by a sudden discrete injury or ischemic insult (eg, stroke, spinal cord injury), the upregulated receptors eventually regress, and the patient can safely receive succinylcholine beginning 6 months after the original insult.

Potassium release does not occur to any significant extent in the general population. Succinylcholine is not contraindicated in renal failure but probably should not be used in patients with known or presumed hyperkalemia (often in the setting of missed

Succinylcholine has rarely been reported to cause masseter spasm, primarily in children and young adults. The clinical significance of this phenomenon is unclear, but administration of a competitive NMBA terminates the spasm. Severe persistent spasm should raise suspicion of malignant hyperthermia.

**Malignant Hyperthermia.** Succinylcholine has been associated with malignant hyperthermia, a perplexing syndrome of rapid temperature rise and rhabdomyolysis. Malignant hyperthermia occurs in genetically predisposed individuals who receive certain volatile anesthetic agents or succinylcholine. The condition is extremely rare and has not been reported in the context of ED intubation. Treatment consists of cessation of any potential offending agents, administration of dantrolene (1–2.5 mg/kg IV every 5 minutes, to a maximum dose of 10 mg/kg IV), and attempts to reduce body temperature by external means. A national malignant hyperthermia hotline is available for emergency consultation at 1-800-644-9737 (then dial 0).

### Competitive Agents.

Competitive NMABs are classified according to their chemical structure. The aminosteroid agents include pancuronium, vecuronium, and rocuronium. Vecuronium neither releases histamine nor exhibits cardiac muscarinic blockade and is an excellent agent for the maintenance of neuromuscular blockade when this is desirable. Rocuronium is the best agent for use in RSI when succinylcholine is contraindicated. In a study of ED intubations performed with rocuronium or succinylcholine, first-pass intubation success was independent of the NMBA used.

**Rocuronium.** When a patient has a contraindication to succinylcholine, rocuronium bromide is the paralytic agent of choice. At a dose of 1.0–1.2 mg/kg IV, rocuronium achieves intubating conditions similar to those of succinylcholine, lasts approximately 50 minutes, and has been used in the ED with success. **Intubating level paralysis may take 15 to 20 seconds longer than with succinylcholine, and the operator should allow 60 seconds to elapse before attempting intubation when rocuronium is used.** There are no absolute contraindications to rocuronium. In the ED, dosing in morbidly obese patients should be based on actual TBW. Although adequate intubating conditions can be obtained when ideal body weight (IBW) is used, this concept is only pertinent to the anesthesiologist who may be titrating neuromuscular blockade to a short anesthetic time. Paralysis will be of sufficient duration, regardless of which weight-based dosing regimen is used, that the emergency clinician will need to have managed the airway successfully before spontaneous respirations return. The potential for inferior intubating conditions using IBW dosing makes this approach undesirable. However, in the subset of critically ill patients who require frequent, serial, neurologic examinations, the more prolonged duration of paralysis with rocuronium may make it less desirable than succinylcholine for routine use.

**Paralysis After Intubation.** After intubation, prolonged paralysis may be desired to optimize mechanical ventilation; however, current management is based on use of deep sedation and analgesia, with neuromuscular paralysis used only when necessary to maintain ventilatory control. If neuromuscular blockade is required, vecuronium (0.1 mg/kg IV) can be given, but longer term neuromuscular blockade is not to be undertaken without ensuring appropriate sedation and analgesia of the patient and a means to ensure that ongoing sedation and analgesia are adequate. Prolonged paralysis without adequate sedation occurs in up to 20% of patients following RSI in the ED. A sedating dose of a benzodiazepine, such as midazolam (0.1 mg/kg IV), combined with an opioid analgesic, such as fentanyl (3–5 µg/kg IV) or morphine (0.2–0.3 mg/kg IV), is required to improve patient comfort and decrease sympathetic response to the ETT. A sedative strategy using propofol (0.1 mg/kg/min IV) is common, especially in head-injured patients, because of its beneficial cerebroprotective profile and rapid resolution of anesthesia that allows frequent neurologic reassessments. With appropriate attention to achieving optimal sedation and analgesia, ongoing use of an NMBA usually is not necessary.

### Induction Agents

A patient with any degree of clinical responsiveness, including reactivity to noxious stimuli, should receive a sedative or induction agent at the time of administration of any NMBA. Patients who are deeply unconscious and unresponsive may require only a reduced dose of an induction agent if the unconscious state is caused by drugs or alcohol, which are themselves general anesthetic agents. Patients who are unconscious because of a central nervous system insult should receive a full induction dose of an appropriate agent to attenuate adverse responses to airway manipulation. Induction agents also potentiate the effect of the NMBA and improve intubation conditions because the intubation is often initiated on the leading edge of paralysis, and the relaxation effects of the induction agent are additive to those of the NMBA.

**Etomidate.** Etomidate is an imidazole derivative that has been in use since 1972. Its activity profile is similar to that of thiopental, with rapid onset, rapid peak activity, and brief duration, but it is remarkable in its lack of adverse hemodynamic effects. Emergency clinicians have high confidence in etomidate and, over the last decade, have chosen it for more than 90% of all ED intubations. The induction dose is 0.3 mg/kg IV. Because etomidate is able to decrease ICP, cerebral blood flow (CBF), and cerebral metabolic rate without adversely affecting systemic mean arterial blood pressure and cerebral perfusion pressure (CPP), it is an excellent induction agent for patients with elevated ICP, even in cases of hemodynamic instability. Etomidate may cause brief myoclonus, but this is of no clinical significance when administered for RSI. A single dose of etomidate has been shown to reduce serum cortisol levels transiently and blunt the adrenal response to adrenocorticotropic hormone (ACTH) by reversibly inhibiting 11β-hydroxylase, a key synthetic enzyme in the glucocorticoid pathway. Since discovering this mechanism, much debate has emerged regarding etomidate’s impact on survival in sepsis patients. Data from retrospective studies are conflicting, but a recent meta-analysis of 18 prospective observational and controlled trials has shown no mortality effect from a single dose of etomidate in septic patients. Recent prospective randomized trials looking at undifferentiated ICU admissions and those specifically involving individuals with septic shock have shown that single-dose etomidate has no effect on outcome. Ironically, much of the original criticism of etomidate arose from the hypothesis that the adrenocortical response to exogenous corticotropin predicts outcome in patients with septic shock, a theory that has since been discredited. The most comprehensive study of the role of exogenous corticosteroids in septic shock has failed to show any benefit, casting further doubt about any possible mortality effect of a single dose of etomidate. Pending a properly constructed, prospective, randomized clinical trial, there is not sufficient evidence to support the recommendation that etomidate be avoided in patients with septic shock. In fact, etomidate’s superior hemodynamic profile makes it an excellent choice in these and other unstable patients.

**Ketamine.** Ketamine, a phencyclidine derivative, has been widely used as a general anesthetic agent since 1970. After an IV dose of 1 to 2 mg/kg, ketamine produces loss of awareness within 30 seconds, peaks in approximately 1 minute, and has a clinical
duration of 10 to 15 minutes. As a dissociative anesthetic agent, ketamine induces a cataleptic state rather than a true unconscious state. The patient has profound anesthesia but may have her or his eyes open. Protective airway reflexes and ventilatory drive usually are preserved.

The principal uses of ketamine in emergency airway management are as a sedative agent for awake intubation (eg, flexible bronchoscope) and as the induction agent during RSI for patients with acute severe asthma or hemodynamic instability. Because of its superior hemodynamic profile, ketamine is an excellent alternative to etomidate for a hemodynamically unstable patient, such as a patient with sepsis or multiple trauma. Although comparative human evidence is lacking, ketamine probably has less propensity to exacerbate hemodynamic instability than any other agent, even etomidate. However, all sedative induction agents, including ketamine, can provoke further hypotension or cardiovascular collapse in patients with profound refractory shock or those with depressed myocardial contractility and catecholamine depletion. In these settings, dosages are reduced to 50% or 25% of the usual dose. In patients with status asthmaticus, etomidate, propofol, or another induction agent can be used, with the notable exception of sodium thiopental, which releases histamine. Ketamine has some bronchodilatory effects and also can cause catecholamine release, so it may be useful for intubation and intermittent administration as part of sedation for mechanical ventilation in patients with severe asthma, although no outcome studies have clearly demonstrated its superiority.

Controversy exists regarding the use of ketamine in patients with elevated ICP because it may increase the cerebral metabolic rate, ICP, and CBF. The evidence that ketamine can produce harm in this way is conflicting, however, and may be outweighed in trauma patients because of its overall favorable hemodynamic profile. Ketamine does not appear to be harmful in children when given in procedural doses to patients with known elevated ICP and may actually lower ICP.

Because it may cause release of catecholamines and increase blood pressure, ketamine should be avoided in traumatic brain injury (TBI) patients with elevated blood pressure. However, we recommend the use of ketamine or etomidate during RSI for induction of patients with TBI and hypotension or risk factors for hypotension. Ketamine may produce unpleasant emergence phenomena, especially disturbing or frightening dreams in the first 3 hours after awakening. These reactions, which are more prominent in adults than in children, in women than in men, in patients receiving larger doses, and in certain personality types, may be mitigated by benzodiazepine administration. Patients who undergo RSI with ketamine should receive a benzodiazepine (eg, lorazepam, 0.05 mg/kg, or midazolam, 0.1 mg/kg) as part of post-intubation management.

**Propofol.** Propofol is a highly lipophilic alkylphenol with γ-aminobutyric acid (GABA) receptor stimulation activity. Its primary use in the emergency setting has been for postintubation sedation in head-injured patients; however, it increasingly has been used as an induction agent during RSI. It reduces ICP and cerebral oxygen usage and is indicated for patients with elevated ICP caused by a medical or traumatic emergency. Because of the propensity of propofol to cause hypotension through vasodilation and direct myocardial depression, the dosage is reduced or the drug is avoided altogether in hemodynamically compromised patients. The usual induction dose of propofol is 1.5 mg/kg IV, but reduced dosages should be used in older patients or those with hemodynamic compromise or poor cardiovascular reserve. Propofol is delivered in a soybean oil and lecithin vehicle and should not be used for patients with allergies to these substances. Although propofol has traditionally been avoided in patients with egg allergy, it is likely safe unless a history of anaphylaxis to egg protein exists. Propofol causes pain at the site of administration in as many as 60% of patients. Using a proximal (antecubital) vein in lieu of a distal venous injection site is the most important preventive measure. Pretreatment with IV lidocaine, coadministration of lidocaine mixed with propofol, and pretreatment with opioids or ketamine have all been shown to limit this common adverse reaction.

**Other Induction Agents.** Given the widespread acceptance and familiarity with etomidate, propofol, and ketamine, other drug classes such as barbiturates and benzodiazepines are frequently used as induction agents for RSI. In North America, nearly all emergency intubations are performed with one of those three agents. Rapidly acting barbiturates, such as thiopental, are highly lipid-soluble and readily cross the blood-brain barrier, acting on the GABA receptor neuroinhibitory complex to depress central nervous system activity. The last US-based manufacturer of sodium thiopental stopped production, and imports into the United States are severely restricted, but it is still in use in some areas outside of North America. Of the benzodiazepines, only midazolam is used as an induction agent, a role for which it is inferior to other, more commonly used agents, such as etomidate and propofol. The usual induction dose for midazolam is 0.2 to 0.3 mg/kg IV. At a dose of 0.3 mg/kg IV, midazolam produces loss of consciousness in about 30 seconds (but may take up to 120 seconds) and has a clinical duration of 15 to 20 minutes. Midazolam is a negative inotrope and should be used with caution in hemodynamically compromised and older patients, for whom the dose can be reduced to 0.1 or 0.05 mg/kg. Onset is slower at these reduced doses.

Dexmedetomidine (Precedex) has gained popularity as a sole agent, or in combination with benzodiazepines, for procedural sedation and awake intubation. The typical loading dose is 1 mg/kg IV over 5 to 10 minutes. At therapeutic levels, it has a minimal effect on the respiratory drive or protective airway reflexes but its use is limited by bradycardia and hypotension. It has not been studied as an induction agent during RSI, and its slow loading rate would likely keep it from being effective in that situation.

**Special Clinical Circumstances**

This section will discuss several specific clinical scenarios that often warrant modification of the airway management plan. Pediatric airway management is discussed in Chapter 161.

**Status Asthmaticus.** RSI is the recommended technique for intubation of a patient in status asthmaticus. Difficult airway considerations are complex in an asthmatic patient because of impending respiratory arrest and the patient’s inability to tolerate attempts at awake intubation. When a difficult airway is identified, intubation preparation should begin early, so that awake methods, such as flexible endoscopic intubation, may be retained as options. Even when a difficult airway is identified in an asthmatic patient, however, RSI usually is the intubation method of choice. Ventilation with a BMV or EGD may be difficult because of high airway resistance, and the technique should be optimized with the use of a low tidal volume and respiratory rate, with a high inspiratory flow rate. Reducing the respiratory rate to allow for adequate exhalation, even at the expense of retaining CO2, is recommended to prevent the development of auto-PEEP, known as breath stacking, which can compromise ventilation and cause barotrauma.

The asthmatic patient has highly reactive airways, and steps should be taken to minimize any additional bronchospasm that may occur during intubation. The bronchoconstriction that occurs with ETT placement is thought to be neurally mediated,
and local anesthetics, particularly lidocaine, have been studied as a way to blunt this airway reflex. We had previously recommended lidocaine to suppress the reflexive bronchospasm and coughing that occurs in response to airway manipulation in asthmatic patients, but there have been no high-level human studies supporting these beneficial effects, particularly in patients who have received a β₂-agonist. High-dose, inhaled β₂-agonists, such as albuterol, provide maximal protection against reactive bronchospasm during intubation and are indicated for asthmatics with or without active bronchospasm. Ketamine has bronchodilatory properties and may mitigate bronchospasm in patients who are not intubated and in patients who are already intubated and are not improving with mechanical ventilation. Although studies to date have been limited, ketamine is also a reasonable induction agent for the emergency intubation of patients with status asthmaticus (Table 1.3).

### Hemodynamic Consequences of Intubation

Laryngoscopy and intubation are potent stimuli for the reflex release of catecholamines. This RSRL produces a modest increase in blood pressure and heart rate and is of little or no consequence in otherwise healthy patients. The RSRL is of potential clinical significance in two settings, acute elevation of ICP and certain cardiovascular diseases (eg, intracerebral hemorrhage, subarachnoid hemorrhage, aortic dissection or aneurysm, ischemic heart disease). In these settings, the reflexive release of catecholamines, increased myocardial oxygen demand, and attendant rise in mean arterial blood pressure and heart rate may produce deleterious effects. The synthetic opioids (eg, fentanyl) and β-adrenergic blocking agents (eg, esmolol) are capable of blunting the RSRL and stabilizing heart rate and blood pressure during intubation. In patients at risk from acute blood pressure elevation, administration of fentanyl (3 µg/kg) during the pretreatment phase of RSI attenuates the heart rate and blood pressure increase. The full sympatholytic dose of fentanyl is much higher, but limiting the dose minimizes the likelihood of precipitating or worsening hypoventilation. Because fentanyl reduces sympathetic tone, it should not be given to patients with hemodynamic compromise (eg, bleeding, volume depletion, sepsis). The administration of 3 µg/kg is safer than larger doses and can be supplemented with an additional 3 µg/kg immediately after intubation if greater sympathetic blockade is desired or hypertension and tachycardia persist. Fentanyl should be given over 60 seconds to prevent hypoventilation or apnea.

#### Elevated Intracranial Pressure

When the ICP is elevated as a result of head injury or acute intracranial catastrophe, there are two considerations—maintaining CPP (by avoiding excessive hypotension) and minimizing supranormal surges in the mean arterial blood pressure (MAP), which can increase ICP. Normally, cerebrovascular autoregulation maintains a constant CBF over a wide range of systemic blood pressures, but this action may be lost in conditions that elevate ICP. Maintenance of the systemic MAP at 100 mm Hg or higher supports CPP and reduces the likelihood of secondary injury. Therefore, the RSI induction agent for a patient with suspected elevated ICP should be selected and dosed to minimize the likelihood of exacerbation of hypotension. In patients with suspected or documented elevation of ICP, control of RSRL is desirable to avoid further elevation of ICP. Fentanyl (3 µg/kg) given as a pretreatment drug is the best choice for this purpose in the emergency setting.

Although evidence has suggested a separate reflex that increases ICP in response to laryngoscopy and intubation, and IV lidocaine was formerly recommended for this purpose, evidence is weak, and no further evidence has developed. Therefore, we no longer recommend lidocaine in this setting. Similarly, RSRL and the ICP response to intubation make blind nasotracheal intubation inadvisable for brain injury patients.

In emergency patients who may have elevated ICP, the emergency clinician should choose an induction agent that balances a favorable effect on cerebral dynamics and ICP with a stable systemic hemodynamic profile. We recommend etomidate, although propofol is also a good option when there is no hemodynamic compromise (Table 1.4).

#### Hypotension and Shock

In critically ill and injured patients, induction agents have the potential to exaggerate preexisting hypotension and, in some cases, precipitate circulatory collapse. Peri-intubation cardiac arrest, typically pulseless electrical activity (PEA), complicates up to 4% of emergency RSIs. Risk factors in ED populations include advanced age (>70 years), COPD, and shock on arrival. In patients with profound shock, all induction agents have the potential to exacerbate hypotension. Shock-sensitive RSI hinges on three primary management principles—volume resuscitation prior to induction (if time permits), reduced dose induction agent administration, and pretreatment with peri-intubation pressor agents (Table 1.5).

When time allows, patients with hypotension should be administered isotonic fluid boluses or packed red blood cells (PRBCs) to maximize preload, increase blood pressure, and allow more pharmacologic options during RSI. Phenylephrine hydrochloride (Neo-Synephrine; 50–100 µg IV push) administered prior to the induction agent can limit hypertensive effects. In addition, induction agent selection should be limited to etomidate or ketamine only, and the dose should be reduced by 50%. Attention to these details can reduce the incidence of cardiovascular peri-intubation adverse events.

Potential Cervical Spine Injury

Historically, most patients with suspected blunt cervical spine injury were intubated orally by direct laryngoscopy with in-line cervical spine immobilization, whether done as an awake procedure or with neuromuscular blockade. However, with this approach, glottic views can be inadequate, and excessive lifting force often is required. Patients with known cervical spine fractures are optimally managed with a flexible bronchoscope to minimize cervical spine motion; however, in the emergency setting, a videolaryngoscope should be used and, if not available, a direct laryngoscope also can be used. A videolaryngoscope provides superior laryngeal views without excessive lifting force or cervical spine movement and has higher intubation success rates when compared with conventional direct laryngoscopy.

The intubating laryngeal mask airway (ILMA) also may result in less cervical spine movement during intubation than direct laryngoscopy, although the need for a blind intubation devices has been decreasing with the advent of videolaryngoscopy. Other devices have also shown promise for safe intubation of patients with cervical spine injury. A fluoroscopic study in which intubation with the Shikani optical stylet (SOS; Clarus Medical, Minneapolis) was compared with DL has shown significantly less cervical spine movement with the SOS but a slightly longer intubation time (28 vs. 17 seconds). Video-enhanced rigid stylets, such as the Clarus Video System (CVS) are also effective tools for patients in cervical collars. The Airtraq and Pentax Airway Scope are curved intubation devices that integrate an ETT channel and either a viewing lens or a video screen to facilitate intubation. Both devices have shown high levels of intubation success and minimal cervical spine motion compared with direct laryngoscopy. In the absence of a coexistent blunt traumatic mechanism or a neurologic examination indicating spinal cord injury, cervical spine immobilization for intubation of patients with penetrating head and neck trauma rarely is indicated. It is not proven whether patients with gunshot or shotgun injuries to the head or neck are at risk of exacerbation of cervical cord injury during intubation, and there is no report of such a patient, with or without clinical evidence of spinal cord injury, who was injured by intubation. In addition, cervical spine immobilization in patients with penetrating neck injuries may be harmful. A large retrospective review of more than 45,000 trauma patients with penetrating injuries has found that those in whom prehospital cervical collars were applied were two to three times more likely to die. Delays in transport and patient assessment and added difficulty for airway procedures were postulated as potential contributors.

Airway Devices and Techniques

Direct Versus Video Laryngoscopy

The inherent limitations of DL make glottic visualization less likely when compared to video instruments. Videolaryngoscopes offer the ability to visualize the glottis without creating a direct line of sight, thus making irrelevant many of the issues that complicate DL. Although DL remains an acceptable technique for tracheal intubation, there is mounting evidence of the clear superiority of modern video devices, and DL increasingly is relegated to the role of a standby device.

Videolaryngoscopes

Modern laryngoscopes incorporate video imaging into specially designed laryngoscope blades to provide glottic visualization superior to that of a direct laryngoscope, without the need to create a straight-line visual axis through the mouth. Videolaryngoscopes can be separated into two large groups based on shape—those that use traditional laryngoscope geometry complemented by a video viewing device (which also can be used as direct laryngoscopes), and those with specially curved or angulated blades, designed specifically for use in a video system and not suitable for DL. This classification system is important because intubating mechanics and success differ between the two groups. Nevertheless, regardless of type, videolaryngoscopes provide superior glottic views and greater first-pass success when compared with direct laryngoscopes, particularly when the airway is difficult or when a nonexpert operator is performing the intubation.
For routine intubation of nondifficult airways by expert intubators, success rates with direct laryngoscopy often can match those obtained with a videolaryngoscope. Because emergency intubations are by definition emergent and cannot be rescheduled, operator experience varies, and airways are often difficult, videolaryngoscopy is the first-choice modality for emergency intubations.

The GlideScope videolaryngoscope system (GVL; Verathon, Seattle) uses a modified Macintosh blade with a straightened, angulated, and elongated tip enclosing a proximally placed camera to provide a wide-angle view of the glottis and surrounding anatomy, even in patients with difficult airways. Video images are transmitted to a high-resolution display that can record still pictures and video clips. Handle and blade sizes range from neonate to obese adult. The GlideScope Ranger is an ultraportable version of the device, designed for use in the out-of-hospital environment. One large series of out-of-hospital intubations has shown that the Ranger significantly reduces the number of attempts needed to intubate compared with DL.6 It consists of a flexible video wand insert that fits inside a disposable, single-piece transparent blade called a stat and comes in sizes comparable to those for the standard GlideScope. The added bulk created by the stat can make it harder to maneuver in emergency patients and may reduce intubation success compared to the standard GVL blade.7 The newest generation GlideScope handles are made of lightweight titanium, with a narrower side profile (Fig. 1.13). The placement of the camera distally along the blade to create a viewing field essentially negates the obstructive potential of the tongue, so GlideScope laryngoscopy and most other hyper-angulated videolaryngoscopy is performed with the blade introduced in the midline of the mouth and advanced around the tongue, with very little lifting. A proprietary rigid, preformed stylet is available for use with the GlideScope, or a malleable stylet can be shaped to match the exaggerated curve of the GlideScope blade. The rigid stylet is less likely to deform during intubation attempts and allows the operator better ETT control on the video screen. Either stylet may be used, and data are conflicting regarding the advantage provided with a rigid stylet; however, one ED-based investigation has suggested that intubation success is higher with the rigid stylet compared with a standard malleable stylet.8 When compared with DL, the GlideScope provides an equivalent or superior glottic view and has a very high intubation success rate.9 Traditional predictors of difficult direct laryngoscopy likely will not apply to videolaryngoscopy because most are based on limitations of creating a direct line of sight, which is not part of videolaryngoscopy.10

Although the view is universally better with all videolaryngoscopes, the GlideScope’s impact on first-pass success has been less clear. A recent large meta-analysis of more than 12 studies has shown that GVL is superior in obtaining full glottic views but, for experienced laryngoscopists, first-pass success was not superior to conventional laryngoscopy. In ED patients, GVL was associated with a lower first-attempt success rate than DL, although the groups were not matched.11 Single-center ED observational studies, however, have shown that the GlideScope is superior to DL for intubating ED patients, and success has increased over time.12,13 The GlideScope causes less cervical spine movement than conventional DL and provides better glottic exposure in patients with strict cervical spine precautions. The C-MAC videolaryngoscope (Fig. 1.14; Karl Storz Endoscopy, Tuttingen, Germany)
incorporates a complementary metal oxide semiconductor (CMOS) video chip into a range of laryngoscope blades to enhance glottic views. Images are displayed on a high-resolution monitor, with image- and video-saving capabilities. The traditionally shaped C-MAC blade can be used as a direct laryngoscope by a trainee while a supervisor observes the video output, providing an excellent tool for teaching DL. One ED-based direct comparison of the C-MAC and GVL has suggested that they perform similarly during emergency intubation. Compared to DL the C-MAC provides better visualization of the glottic inlet, higher rates of first-pass success, and outperforms DL when rescuing a failed first attempt using DL.

The King Vision videolaryngoscope (King Systems, Noblesville, IN) is a single-use, lightweight device with a detachable (and reusable) screen that sits on top of a disposable video blade (Fig. 1.15). There are two blade types, one with an integrated tube channel and one without; the latter requires the operator to place the ETT manually. In simulated difficult airways using cadaveric subjects, the King Vision results in higher success rates and faster tube placement compared to DL. The McGrath Series 5 is a cordless videolaryngoscope with an integrated screen and handle configuration.

There are several other models of videolaryngoscopes with various sizes and features, such as disposable sheaths or blades, and at various price points. Individual evaluation of these devices is important in selecting the best videolaryngoscope for an individual practitioner or practice group. In 2012, videolaryngoscopes were chosen as the first device for airway management in nearly 40% of all intubations. Overall, videolaryngoscopy offers the promise of transforming laryngoscopy and has the potential to render DL obsolete.

Fiberoptic and Video Intubating Stylets

Several semirigid fiberoptic and video intubating stylets also are available. The SOS is the most studied of these, although a newer version, the Levitan scope (Clarus Medical), uses a light-emitting diode (LED)–illuminated fiberoptic stylet to facilitate intubation by direct laryngoscopy. The device is recommended by the manufacturer to facilitate first-pass success when a limited glottic view is obtained by DL. In the only study comparing the Levitan scope with the gum elastic bougie, however, the two devices achieved similar success.

Flexible Intubating Scopes

Intubation using a flexible endoscope is an important option for certain difficult airways, particularly in those with distorted upper airway anatomy, such as angioedema or blunt anterior neck trauma. These scopes long relied on fiberoptic technology, but this has largely been supplanted by miniaturized, high-quality video systems. After appropriate patient preparation, the endoscope is passed through the vocal cords under continuous visualization, serving as an introducer for an ETT, which is then placed through the glottis. Flexible endoscopic examination also is used for airway assessment to determine whether intubation is needed, such as for patients with smoke inhalation or supraglottitis. Intubation of morbidly obese patients, those with distorted airway anatomy (eg, penetrating or blunt anterior neck injury), or those with a fixed cervical spine deformity can be achieved with the flexible endoscope with topical anesthesia and judicious sedation, thus preserving the patient’s ability to breathe until intubation has been achieved. Scopes also have been used successfully to intubate through an ILMA, and video systems likely would work well in this application also.
CHAPTER 1
Airway

There is a significant learning curve for flexible endoscopic intubation, and proficiency with this device requires training and practice. Fortunately, endoscopic examination of the upper airway to the level of the vocal cords is a similar skill set as that needed to maneuver the scope through the cords to intubate. This is an important alternative method to obtain real-life experience with insertion and manipulation of the scope. Only approximately 1% of ED patients are managed with a flexible bronchoscope, possibly reflecting reluctance to select this instrument if the operator does not feel sufficiently trained or competent. Flexible bronchoscope intubations are the method of choice for most patients with upper airway obstruction. The role of flexible endoscopic intubation in the ED will likely expand as obesity increases in the population and, increasingly, difficult airways are handled in the ED without backup. The transition from fiberoptic to CMOS video technology will make these flexible scopes more durable and less prone to fogging, both desirable attributes for emergency intubation. Although the cost required to purchase and maintain a flexible endoscope can make it challenging for some emergency departments, single-use flexible videoscopes, such as the Ambu aScope (Ambu, Columbia, MD), provide a less costly option (Fig. 1.19). Emergency clinicians should have immediate access to flexible endoscopes and should acquire training and regular practice in their use.

Extraglottic Devices

Laryngeal Mask Airways. LMAs collectively include a number of commercially available ovoid, silicone mask devices designed to seal above the glottis and permit ventilation through a central channel with a standard bag. There are several models available, and attributes differ among the models, but use and success rates are very similar. The most widely used is the original LMA. Reusable and single-use configurations, conventional and intubating formats, are offered by several manufacturers. The mask is inserted blindly into the pharynx and then inflated, providing a seal that permits ventilation of the trachea with minimal gastric insufflation. In elective anesthesia, the LMA has an extremely high insertion success rate and low complication rate, including a low incidence of tracheal aspiration. Evaluations of LMA insertion by experienced and inexperienced personnel consistently have shown ease of insertion, high insertion success rates, and successful ventilation. The LMA may be a viable alternative to endotracheal intubation for in-hospital or out-of-hospital treatment of cardiac arrest, particularly when responders are inexperienced airway managers. At a minimum, the device may serve a temporizing role equal or superior to BMV until definitive airway management can be achieved. The LMA Supreme (Teleflex Inc., Morrisville, NC) is a more robust LMA with a rigid angled tube, similar to an ILMA; it offers an orogastric tube channel and higher seal pressures than the standard LMA. This likely is the best version for general ED use.

A noninflatable LMA, the i-gel (Intersurgical, Berkshire, England), has a viscous gel cuff and does not require inflation (Fig. 1.19). It is available in a variety of sizes for adults and pediatric patients. The device is placed blindly, and insertion depths are marked on the side of the device. It has an integrated bite block and channel for passage of an orogastric tube. Initial experience with the device, even with minimally trained novice users, has been promising, with high insertion success rates and shorter insertion times when compared with the LMA or laryngeal tube airway.10

The ILMA is designed to facilitate intubation through the mask after correct placement (Fig. 1.21). It differs from the LMA in two main ways. First, the mask is attached to a rigid, stainless steel ventilation tube that is curved almost to a right angle, and the mask incorporates an epiglottic elevator at its distal end. Placement of the ILMA results in successful ventilation in almost 100% of cases and successful subsequent intubation in 95%. The ILMA can also be used for ventilation and intubation in obese patients, with similarly high success rates. The ILMA has a special ETT and stabilizer rod to remove the mask over the ETT.
after intubation has been accomplished, but intubation can be comparably successful with a conventional polyvinylchloride (PVC) ETT.

The ILMA is a better device than the standard LMA for use in the ED because it facilitates rescue ventilation and intubation. Intubation through the ILMA has compared favorably in terms of success with DL and is superior in the hands of novice intubators. When the ILMA is placed, intubation can be performed blindly or guided by a lighted stylet or fiberoptic scope. The ILMA comes only in sizes 3, 4, and 5 and so is not suitable for use in patients weighing less than about 30 kg (=66 lb). For smaller patients, the standard LMA, which has sizes down to size 1 (infant), should be used. Intubation can be achieved through the standard LMA, but the success rate is significantly less than with the ILMA. As experience with the LMA and ILMA grows, it is likely that there will be increasing adoption of the LMA as a primary airway management technique by nonhospital first responders, and the ILMA has been gaining attention as a primary rescue device in the ED. Newer LMA-style devices, the Ambu air-Q and Aura-I, can act as standard LMAs for ventilation and oxygenation but can facilitate blind intubation with standard adult endotracheal tubes. Both work well intubating a difficult airway, especially when augmented by flexible endoscopy.

In the ED, the primary use of the LMA or ILMA is as a rescue technique to provide a temporary airway when intubation has failed, bag ventilation is satisfactory, and the patient has been paralyzed and may require prolonged ventilation or be in need of immediate airway management. In such cases, the LMA is one of numerous acceptable devices. In the can’t intubate, can’t ventilate situation, cricothyrotomy is indicated, but an ILMA may be placed rapidly in an attempt to achieve ventilation (converting the situation to can’t intubate, can ventilate), as long as this is done in parallel with preparations for cricothyrotomy and does not delay initiation of a surgical airway. The standard LMA may also offer advantages for providing ventilation in unconventional positions, such as when the patient is lying on his or her side. In the out-of-hospital setting, where concerns about esophageal placement of ETTs have focused interest on methods used for airway management, the LMA and Combitube offer excellent placement and ventilation characteristics and may be preferable to endotracheal intubation in this setting, especially when intubation is relatively infrequently performed. If the patient is in a difficult position in terms of intubation access, the LMA may facilitate more rapid ventilation.

Other Extraglottic Devices. In addition to LMAs, which sit above the glottis, there are several other types of EGDs. These are inserted blindly posterior to and beyond the laryngeal inlet to provide oxygenation and ventilation through side ports while inflatable balloons occlude the pharynx above and the esophageal inlet below. Because of their positioning behind the larynx, these are often called retroglottic devices. The prototype for these devices is the esophagotracheal Combitube. The Combitube is a plastic double-lumen tube with one lumen functioning as an airway after esophageal insertion and the other lumen functioning as a tracheal airway. The tube is placed blindly into the esophagus, and proximal and distal balloons are inflated sequentially through different ports. The balloons prevent escape of ventilatory gases upward through the pharynx or downward through the esophagus. The tube is placed into the esophagus, as designed, almost 100% of the time, but both lumens are patent, so ventilation is still possible if the tube has been placed inadvertently into the trachea. It comes in two sizes and is used only in patients taller than 48 inches.

The King laryngeal tube airway (King LT; King Systems) has a single port through which distal and proximal low-pressure balloons are inflated as a single step (Fig. 1.22). The distal balloon, when seated correctly, obstructs the cervical esophagus, and the larger proximal balloon obstructs the hypopharynx, preventing regurgitation of air. A newer version of the King LT has a posterior channel that accepts a nasogastric tube, which can be passed through the device into the stomach for aspiration of gastric contents. The King LT is disposable, rapidly placed, easy to use by operators of various skill levels and has seal pressures similar to those of standard LMAs. All retroglottic devices can be safely left in place for 4 hours without mucosal pressure damage. Another device, the Rusch EasyTube (Teleflex, Morrisville, NC), is similar in concept and appearance to the Combitube but is available in 41 Fr and a smaller 28-Fr size for smaller patients. All retroglottic devices are primarily a substitute for endotracheal intubation for non–ETT-trained personnel, but are also used by advanced airway managers as a way to oxygenate and ventilate patients during crash and failed airway scenarios. These devices should be considered temporary measures, do not protect against aspiration, and should be exchanged for a definitive airway as soon as possible.
Surgical Airway Management

Needle Cricothyrotomy With Transtracheal Jet Ventilation

With the advent of newer airway devices, especially videolaryngoscopes, surgical airway management, which always has been distinctly uncommon, is required even less frequently. Needle cricothyrotomy, which involves the insertion of a large needle (ideally, a large catheter designed for this purpose) through the cricothyroid membrane into the airway for transtracheal ventilation, may have a limited role in pediatric airway management (see Chapter 161). However, it is rarely, if ever, the right choice for an adult airway emergency and will not be discussed further here.

Cricothyrotomy

Cricothyrotomy is the creation of an opening in the cricothyroid membrane through which a cannula, usually a cuffed tracheostomy tube, is inserted to permit ventilation. The techniques and variations thereof have been well described elsewhere.54 When surgical airway management is required, cricothyrotomy is the procedure of choice in the emergency setting, where it is faster, more straightforward, and more likely to be successful than tracheotomy.

Cricothyrotomy is indicated when oral or nasal intubation is impossible or fails and when BMV or EGD cannot maintain adequate oxygen saturation (the can’t intubate, can’t ventilate situation). Previous large series have established that the incidence of cricothyrotomy is approximately 1% of all ED intubations, with the highest rates seen in trauma patients.16 More recent ED-based intubation surveillance has suggested that the rate of salvage cricothyrotomy—a surgical airway performed after another technique was attempted first—has dropped and is now approximately 0.3%. Cricothyrotomy is relatively contraindicated by distorted neck anatomy, preexisting infection in the neck, and coagulopathy; these contraindications are relative, however, and establishment of the airway takes precedence over all other considerations. The procedure should be avoided in infants and young children, in whom anatomic limitations make it exceedingly difficult. Studies have suggested that approximately five practice cricothyrotomies on a simulator or animal model are sufficient to achieve at least baseline capability with the procedure, although training intervals for skill maintenance have not been well defined.

OUTCOMES

Phase II of the National Emergency Airway Registry study (NEAR II) of almost 9000 ED intubations has reported that most patients were intubated by emergency clinicians using RSI, with overall success rates of 96%.16 The NEAR classification system characterizes potentially adverse occurrences during intubation as adverse events. In the NEAR study, the overall rate of adverse events was 12%, with recognized esophageal or mainstem intubation and hypotension being the most common.7 Phase III of the NEAR project has reported on more than 17,500 adult ED intubations over an 11-year period (2002–2012).4 This latest multicenter report has revealed that first-attempt success (FPS) was 83%. However, over the course of data collection, this significantly increased from 80% in the first 3 years to 86% during the last 3 years. Emergency clinicians managed 95% of all patients, and 99% were successfully intubated within three attempts. Adverse event rates (12%) were identical to those of NEAR II, with recognized esophageal intubation and hypotension requiring IV fluids being the most common. The incidence of cricothyrotomy dropped from 0.9% to 0.5%. No studies have evaluated the long-term outcome of intubated ED patients.
Anticipating the clinical course of the patient’s condition and assessing the likelihood of deterioration are crucial to the decision to intubate, especially if the patient is to leave the ED for a period of time (eg, interfacility transfer, diagnostic testing).

Assessment of the patient for potential difficulty with intubation, bag-mask ventilation (BMV), ventilation using an extraglottic device (EGD), and cricothyrotomy is an essential step before a neuromuscular blocker is administered. The mnemonics LEMON, MOANS, RODS, and SMART can serve as useful aids.

In the absence of a crash patient (agonal, unresponsive to laryngoscopy) or difficult airway, rapid sequence intubation (RSI) is the airway management method of choice for ED patients.

Tube placement confirmation using end-tidal CO$_2$ (ETCO$_2$) is essential after intubation; failure to detect adequate quantities of exhaled CO$_2$ is evidence of esophageal intubation until proven otherwise.

Videolaryngoscopy has transformed intubation by eliminating many of the traditional anatomic barriers to direct laryngoscopy. Practitioners responsible for emergency airway management should transition their routine airway management from direct laryngoscopy to videolaryngoscopy.

Cricothyrotomy is indicated in the can’t intubate, can’t oxygenate failed airway situation and should be performed without hesitation once this has been identified. Delays may increase the likelihood or severity of hypoxic injury to the patient.

Emergency airway management is evolving, and modern intubators should be aware of these fundamental changes. Videolaryngoscopy is replacing direct laryngoscopy as the tool of choice for emergency airway management. Etomidate is used in more than 90% of all RSI, and rocuronium use has been increasing. EGDs, such as laryngeal mask airways, are continually evolving, offering additional options for rescue oxygenation of the failed airway.

REFERENCES

1.1. Which of the following is considered unreliable for assessing the need to establish an artificial airway?
A. Absence of a gag reflex
B. Absence of swallowing on command
C. Level of consciousness
D. Patient’s ability to phonate
E. Pooling of secretions in the oropharynx

Answer: A. The gag reflex can be absent in up to 25% of normal adults. Moreover, there is no evidence that the presence or absence of a gag reflex corresponds to a patient’s ability to protect his or her airway. It should therefore not be used as an indicator of the need for intubation.

1.2. Which of the following is the most reliable overall method for confirmation of correct tube placement after endotracheal intubation?
A. Bulb aspiration
B. Chest and gastric auscultation
C. Chest radiography
D. Detection of colorimetric or quantitative end-tidal carbon dioxide (ETC02)
E. Measurement of exhaled volume

Answer: D. Detection of ETC02 after endotracheal intubation is the most reliable of the options listed for the confirmation of tube placement. (A fiberoptic scope passed through the endotracheal tube, with visualization of the tracheal rings, is the gold standard but is not generally required.) Limitations of colorimetric CO2 detection should be appreciated in cardiac arrest patients. In these situations, a bulb aspiration device may provide helpful information, even though this technique is generally not as reliable as ETC02 detectors. The other listed options, traditional as they may be, are prone to failure and should not be relied on for confirmation of tube placement.

1.3. During rapid sequence intubation (RSI), what is the optimal time to wait between the administration of a pretreatment drug and administration of the induction agent and neuromuscular blocking agent?
A. 1 minute
B. 2 minutes
C. 3 minutes
D. 4 minutes
E. 5 minutes

Answer: C. Three minutes is considered the optimal time to wait between the administration of a pretreatment drug and administration of the induction agent. If the clinical situation does not allow for this length of time between administrations, there may still be some benefit to administration of the pretreatment agent.

1.4. In which of the following conditions is succinylcholine contraindicated?
A. Acute burn < 5 days
B. Acute head injury secondary to motor vehicle accident
C. Acute spinal cord injury < 5 days
D. Renal failure with a serum potassium level of 4.7 mEq/L
E. Stable multiple sclerosis

Answer: E. Succinylcholine has been associated with severe fatal hyperkalemia when administered in specific clinical circumstances. The risk of succinylcholine-induced hyperkalemia in patients with denervation syndromes begins with the onset of disease and continues indefinitely. With respect to acute burns, trauma, stroke, spinal cord injury, and intraabdominal sepsis, the risk of hyperkalemia with succinylcholine use becomes evident 5 days after the onset of injury or disease process. Succinylcholine is not contraindicated in renal failure; however, known elevations in the potassium level may warrant use of another neuromuscular blocking agent.

1.5. Which of the following conditions prevents reliable use of colorimetric capnometers for the detection of esophageal intubation in 25% to 40% of cases?
A. Acute asthma exacerbation
B. Cardiac arrest
C. Chronic obstructive pulmonary disease exacerbation
D. Head trauma
E. Pneumonia

Answer: B. Colorimetric capnometers detect CO2 and can be used to confirm tracheal intubation. The absence of CO2 detection indicates failure to intubate the trachea and necessitates reintubation, except in the low-perfusion state of cardiac arrest, when quantities of CO2 returned to the lungs may be insufficient to produce a color change in the capnometer. This situation occurs in 25% to 40% of intubated cardiac arrest patients. The placement of the tube needs to be confirmed by clinical means, revisualizing placement, or the tube needs to be removed and the patient reintubated.

1.6. Until how long after an acute burn is succinylcholine considered safe to use for RSI?
A. 30 minutes
B. 12 hours
C. 24 hours
D. 48 hours
E. 5 days

Answer: E. Succinylcholine can produce severe (and fatal) elevations in serum potassium levels after administration in patients with burns. However, this vulnerability to succinylcholine-induced hyperkalemia is not clinically significant until at least 5 days after the acute burn. As a result, succinylcholine remains the paralytic of choice if rapid sequence intubation occurs less than 5 days after the burn.
Mechanical Ventilation and Noninvasive Ventilatory Support

Todd A. Seigel

CHAPTER 2

PERSPECTIVE

Invasive and noninvasive ventilation are essential components in the management of critically ill patients. Some patients require support for respiratory failure or as part of comprehensive management of critical illness, whereas other patients require assistance primarily for airway protection. The reasons for initiating ventilatory support are varied and will influence ventilation strategy, hemodynamics, sedation strategy, and subsequent clinical course.

The decision to intubate is discussed in Chapter 1 and in other chapters throughout this text in the context of individual conditions. This chapter describes the modalities and techniques of noninvasive and invasive mechanical ventilation.

PRINCIPLES OF MECHANICAL VENTILATION

Physiology of Positive-Pressure Breathing

Spontaneous breathing in normal patients is based on the initiation of negative intrathoracic pressure. It is mediated by contraction and relaxation of the diaphragm in concert with the intercostal muscles. Contraction of the diaphragm and intercostal muscles increases the intrathoracic volume, creating negative pressure in the chest cavity and causing inhalation, whereas relaxation of the diaphragm and recoil of the chest wall decreases intrathoracic volume, which increases pressure in the chest cavity and results in passive exhalation. The amount of force required to generate adequate inspiration is influenced by the work of breathing; when the work of breathing increases, patients may be unable to generate enough negative force to sustain successful respiration and will require ventilatory support. Unlike spontaneous breathing, invasive and noninvasive mechanical ventilation are based on the delivery of humidified air with positive pressure. The amount of positive pressure required for adequate ventilation is dependent on the patient’s respiratory effort, ranging from mild assistance to full support. Inhalation occurs by driving air into the lungs under positive pressure; air is passively exhaled when the chest wall recoils.

Transition from negative-pressure breathing to positive-pressure breathing affects cardiovascular and pulmonary physiology and can have significant clinical consequences. Pressure changes in the thoracic cavity directly affect pressures in the chambers of the heart. During spontaneous inspiration, decreased intrathoracic pressure augments venous return and preload. Cardiac output is increased, and there is an increased pressure gradient between the left ventricle and aorta. With the initiation of positive-pressure ventilation (PPV), the opposite occurs—venous return is diminished, cardiac output falls, and there is a decreased pressure gradient between the left ventricle and aorta. Relative hypotension can occur after ventilatory support has been initiated, and this may be exaggerated in patients with clinical hypovolemia or vasodilatory states.

Invasive Mechanical Ventilation: Control Variable and Ventilator Mode

The primary considerations regarding initiation of mechanical ventilation relate to how each breath should be delivered. This includes how a breath is defined, the size, duration, and frequency of the breath, and the degree of interaction the patient has with the ventilator.

How the ventilator defines a breath is referred to as the control variable. The ventilator can give breaths based on delivery of a set pressure or a set volume, referred to as pressure-controlled ventilation (PCV) and volume-controlled ventilation (VCV), respectively. The amount of time over which the breath is delivered is defined as the inspiratory time, and the speed at which air travels through the circuit is defined as inspiratory flow rate.

In PCV, a set amount of pressure is applied to the airway to expand the lungs for a specified amount of time. During PCV, the target pressure and inspiratory time are set by the provider, whereas the delivered tidal volume and inspiratory flow rate vary as functions of dynamic lung compliance and airway resistance. Ability to control the pressure delivered to the lungs is particularly useful to prevent barotrauma, which is described in more detail below. In addition, because inspiratory flow is not fixed, PCV may improve ventilator synchrony in intubated patients with a high respiratory drive. A significant disadvantage of PCV is that as tidal volume changes with acute changes in lung compliance, it can neither be guaranteed nor limited. PCV offers advantages over VCV in clinical conditions in which control of airway pressure is strictly mandated. This includes patients with the potential to develop dynamic hyperinflation and intrinsic positive end-expiratory pressure (PEEP) such as patients with severe asthma or respiratory failure from chronic obstructive pulmonary disease (COPD).

In VCV, a breath is defined by delivery of a set tidal volume to the lungs. Inspiratory volume and flow rate are set by the provider, and inhalation ends once a preset tidal volume has been delivered. The inspiratory time is a function of the set flow rate. Lung pressure—peak inspiratory pressures (PIPs) and end-inspiratory alveolar pressures—vary based on lung compliance and set tidal volume. The main benefit to the use of VCV is the ability to control tidal volume and minute ventilation, but VCV may cause spikes in peak pressures when compliance of the respiratory system is poor. Clinically, poor respiratory system compliance occurs in conditions that increase lung or chest wall stiffness, including pulmonary edema, acute respiratory distress syndrome (ARDS), pneumothorax, and obesity.

The choice between pressure-cycled ventilation and volume-cycled ventilation is driven by the underlying indication for mechanical ventilation. Volume-cycled ventilation should be used when strict control of tidal volume is mandated. Specifically, this includes patients with known ARDS, in whom low tidal volume strategies have been proven to reduce mortality. In addition,
patients with decreased chest wall compliance should be placed on VCV to ensure that adequate tidal volume is delivered. This includes patients with morbid obesity or severe chest wall burns. Conversely, in conditions in which strict control of airway pressure is desired, pressure-cycled ventilation should be used. As detailed earlier, this occurs most often in patients with asthma or COPD. In addition, because inspiratory flow is not limited in pressure-cycled ventilation, this strategy may be preferred to volume-cycled ventilation in patients with a high respiratory drive such as patients with salicylate overdose. For patients who do not require strict control of pressure or volume, similar ventilation mechanics can generally be achieved with pressure-cycled or volume-cycled ventilation (Table 2.1).

Newer ventilators can deliver breaths that combine volume and pressure strategies, referred to as dual-control ventilation. A common dual-control method of ventilation is pressure-regulated volume control (PRVC). A variation of volume control, PRVC is set to deliver a specific tidal volume while simultaneously minimizing airway pressure. Unlike with strict volume control, pressure is measured and modulated by the ventilator with each breath to ensure the delivery of the preset tidal volume. In addition, a pressure limit is set, and the ventilator sounds an alarm when that pressure has been exceeded. Theoretically, this combines the advantages of pressure and volume control to ensure the delivery of a specific tidal volume while the airway pressure is monitored. That said, because the ventilator is set to deliver a specific tidal volume, the disadvantages of volume-cycled ventilation persist. In addition, elevations in airway pressure are still possible and must be addressed if acute changes in respiratory system compliance occur. This mode of ventilation has not been specifically studied but likely does not offer significant advantage over traditional volume- or pressure-cycled ventilation, particularly if strict parameters for airway pressure are desired.

The term ventilator mode refers specifically to the amount of respiratory support provided by the ventilator. The most common ventilator modes can be categorized on the basis of how often the ventilator will initiate a breath for the patient and can be divided broadly into continuous mechanical ventilation (CMV), intermittent mechanical ventilation (IMV), and continuous spontaneous ventilation (CSV). CMV and IMV are intended to provide patients with a specific minimum number of preset breaths as defined by the ventilator and can be delivered via pressure or volume control methods. Conversely, in CSV, no mandatory breaths are delivered to a patient; the size and rate of the breaths are determined by the effort of the patient and are augmented with applied pressure to the airway. These methods are compared in Table 2.2. Other, more complex modes of ventilation include proportional assist ventilation (PAV) and airway pressure release ventilation (APRV), although these generally are not used in the emergency department (ED).

CMV is intended to provide full ventilatory support for patients with little or no spontaneous respiratory activity continuous delivery of preset breaths. However, if a patient generates negative pressure, representing respiratory effort, on CMV, that breath will be assisted by the ventilator. For this reason, CMV is also referred to as assist-control (A/C) ventilation. In this mode, patients can trigger a breath at any rate but will always receive at least the preset number of breaths. Notably, when a patient initiates a breath, the assisted breath that he or she receives is the full volume breath as set on the ventilator. For the promotion of ventilator synchrony, a spontaneous patient-initiated breath will take priority over a preset breath, meaning that if the ventilator is set to deliver 12 breaths/min, a breath is provided every 5 seconds in the absence of spontaneous inspiratory effort. When the patient makes a spontaneous effort, the ventilator provides an additional breath and the timer resets for another 5 seconds. A/C ventilation is the most useful initial mode of mechanical ventilation in ED patients, because many patients are initially paralyzed and sedated and do not interact with the ventilator. One of the biggest challenges with A/C ventilation, however, is that patient-initiated breaths are not proportional to patient effort; when inspiratory effort is detected, a full-sized breath is delivered. Clinically, this requires adequate sedation of patients when ventilated in the A/C mode to prevent spontaneous respiratory efforts that will result in hyperventilation, air trapping, hypotension, and poor ventilator synchrony.

Synchronized intermittent mandatory ventilation (SIMV) provides intermittent ventilatory support to patients by delivering mandatory and spontaneous breaths. In SIMV, a mandatory breath is given at a preset rate, but the breath is synchronized as much as possible with spontaneous patient effort. Similar to A/C, the patient will receive at least the minimum number of preset mandatory breaths; if the patient provides no effort, the preset number of breaths will be given. If a patient has a rate of spontaneous respirations lower than the set rate, the ventilator will provide the preset number of full breaths but will deliver as many as possible in synchrony with patient effort. In these scenarios, there is little difference between A/C and SIMV. If a patient has a rate of spontaneous respirations higher than the preset rate, the patient receives all preset full breaths at the set rate, but additional

breaths generated by the patient will be at a volume determined by his or her respiratory effort. Additional breaths can be given via pressure support (see later). SIMV is useful for patients who are sedated but who have weak respiratory efforts and combats some of the challenges of using A/C in awake patients. The delivery of extra breaths consistent with patient respiratory effort attenuates the effects of air trapping and hyperventilation and may promote patient comfort.

CSV, in contrast to A/C or SIMV, delivers a breath only on a patient-initiated trigger. On a ventilator, the only way to eliminate mandatory delivery of preset breaths is via pressure support ventilation (PSV); therefore, CSV and PSV are essentially the same for patients who remain intubated with no intrinsic spontaneous respiratory effort. PSV is designed to support patients’ spontaneous respiratory effort by delivering an applied pressure to the airway on the trigger of a breath. The amount of pressure required to support a full breath is variable and depends on the patient’s ability to overcome the work of breathing. When inspiratory flow stops, signaling the end of inhalation, pressure support ceases and exhalation is allowed to proceed spontaneously. The level of pressure support is the only parameter determined by ventilator settings; inspiratory flow, inspiratory time, and tidal volume are determined by patient effort. This mode of ventilation most closely resembles normal spontaneous breathing and, for this reason, promotes patient control and comfort. In the ED, PSV is rarely used for intubated patients because most patients who require intubation are unable to breathe spontaneously and effectively and may have failed noninvasive support before intubation. PSV may prove to be most useful in awake and interactive patients who have been intubated for temporary airway protection rather than for respiratory failure. If PSV is used, careful monitoring and ventilatory alarms are needed to ensure against undetected hypoventilation or apnea.

Positive End-Expiratory Pressure

Regardless of the ventilatory mode chosen, PEEP is often used during invasive mechanical ventilation. PEEP refers to the maintenance of positive airway pressure after the completion of passive exhalation. During acute respiratory failure, lung volumes are typically decreased; the application of PEEP increases functional residual capacity (FRC), improves oxygenation, and decreases intrapulmonary shunting. The use of PEEP also reduces portions of nonaerated lung that may contribute to the development of ventilator-induced lung injury. Notably, PEEP increases intrapulmonary and intrathoracic pressures and may affect pulmonary and cardiovascular physiology. Potential adverse effects of PEEP include decreased cardiac output, lung overdistention, and pneumothorax.

Applied PEEP must be specifically differentiated from intrinsic PEEP (iPEEP, or auto-PEEP), which may result from improper assisted ventilation when adequate time is not allowed between breaths for complete exhalation. This is discussed later.

Noninvasive Techniques

Noninvasive positive-pressure ventilation (NPPV) is the delivery of CSV via sealed mask rather than endotracheal tube. As with PSV, the ventilator is set to provide a defined level of pressure when a patient takes a breath; inspiratory flow and inspiratory time are completely patient-mediated. The most common types of noninvasive ventilation in the ED are continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BL-PAP). BiPAP, a term commonly used for BL-PAP, is the proprietary name of a portable device that uses this method of noninvasive ventilation rather than a term for the ventilation itself (Philips Respironics, Murrysville, PA). CPAP provides constant positive pressure throughout the respiratory cycle, whereas BL-PAP alternates between higher pressure during inspiration (IPAP) and lower pressure during expiration (EPAP). Although, strictly speaking, CPAP applies positive pressure to the airway during inspiration, the amount of inspiratory assistance is minimal. Conversely, just as with invasive mechanical ventilation, IPAP augments patient respiratory effort by decreasing the work of breathing during inspiration, whereas EPAP acts as PEEP to maintain FRC and alveolar recruitment. Notably, although PEEP, CPAP, and EPAP all represent positive airway pressure at the end of expiration, PEEP, by convention, refers to pressure applied during invasive mechanical ventilation, whereas CPAP is the application of positive pressure (invasively or noninvasively) during spontaneous breathing. The terms are occasionally used interchangeably.

Decision Making: Noninvasive Versus Invasive Ventilation

The decision to intubate carries significant implications for patients, including potentially life-threatening complications related to airway management and subsequent complications related to intensive care unit (ICU) care. NPPV is an appealing option for patients requiring ventilatory assistance with potentially reversible conditions when tracheal intubation is not immediately necessary or as a therapeutic adjunct for patients with “do-not-intubate” directives. In appropriately selected patients, NPPV obviates intubation in more than 50% of cases and improves survival. Relative contraindications include decreased level of consciousness, lack of respiratory drive, increased secretions, hemodynamic instability, and conditions such as facial trauma that would prevent an adequate mask seal. Although the need for emergent intubation is generally a contraindication to treatment with noninvasive ventilation, noninvasive ventilation has been shown to improve preoxygenation prior to intubation when compared to standard methods of oxygen delivery. If NPPV is initiated, patients should be reassessed frequently for progress of therapy, tolerance of the mode of support, and any signs of clinical deterioration that would indicate a need for intubation.

Patients most likely to respond to NPPV in the ED are those with more readily reversible causes of respiratory distress such as COPD exacerbation or cardiogenic pulmonary edema in which fatigue is a significant factor. Robust evidence has supported the use of NPPV for both conditions. In patients with acute COPD exacerbations, NPPV decreases the need for subsequent intubation with a number needed to treat (NNT) of 4, decreases hospital length of stay, and improves mortality (NNT = 10) when compared with standard therapy. Treatment failure, defined as a subsequent need for intubation, is predicted by a Glasgow Coma Scale score of less than 11, sustained arterial pH less than 7.25, and tachypnea greater than 35 breaths/min. A recent large study has confirmed prior findings regarding the benefit of NPPV over invasive ventilation, but highlighted the need for appropriate patient selection in that a failed trial of NPPV was associated with higher mortality when compared to patients who received immediate intubation.

In patients with acute cardiogenic pulmonary edema (ACPE), NPPV reduces the work of breathing while simultaneously improving cardiac output. The application of NPPV causes elevations in intrathoracic pressure that decrease left ventricular (LV) ejection pressure and LV transmural pressure, which results in afterload reduction. In addition, decreases in RV preload may improve LV compliance via ventricular interdependence. Compared with standard therapy, multiple studies and several meta-analyses have confirmed a decreased need for intubation, as well as decreased mortality for patients with ACPE treated with NPPV. Benefits were found to be independent of whether patients received CPAP or BL-PAP and, despite suggestions from early clinical data, no increased rate of acute myocardial infarction occurred in patients receiving any form of NPPV. Although either modality can be used, a recent ED-based study has suggested faster clinical improvement with BL-PAP. Specific predictors of failure of NPPV in those with congestive heart failure (CHF) have not been systematically examined.

Evidence regarding the use of NPPV in other patients with respiratory compromise, including asthma and pneumonia, is limited. Several small studies have suggested that NPPV may be beneficial for patients with acute asthma exacerbations by improving lung function, decreasing bronchodilator requirements, and shortening overall hospital length of stay, suggesting a potential role for NPPV in these patients. Studies have failed to establish a definitive role for NPPV in pneumonia, and the presence of pneumonia has been shown to be an independent risk factor for failure of noninvasive ventilation. In a recent trial of NPPV for pneumonia, increased heart rate and decreased PaO2/FIO2 ratio after 1 hour of therapy predicted failure of NPPV. In addition, the duration of NPPV prior to intubation was associated with in-hospital mortality, suggesting that early intubation is preferable for patients who do not rapidly improve on noninvasive therapy.

Approach to Initial Ventilator Settings

Noninvasive Ventilation

Initial settings for noninvasive ventilation should be determined by the amount of ventilatory assistance required by the patient, as well as patient comfort and cooperation with therapy. The first consideration in the use of NPPV is whether to provide support in the form of CPAP or BL-PAP. As described earlier, there is no clear benefit of one over the other. Support may be provided by a full-face (oronasal) mask or nasal mask; this choice is determined by patient comfort, ability of the patient to cooperate, and the need for the patient to cough effectively or speak. Notably, nasal masks have been associated with higher leak rate and decreased patient comfort; therefore, I recommend a full-face mask as the first method for novice patients. Inspiratory support (IPAP) is initiated at 10 cm H2O and expiratory support (EPAP) at 5 cm H2O. Subsequent titration of these parameters is based on the patient’s clinical response, particularly pressure tolerance, respiratory rate, and oxyhemoglobin saturation. Although blood gas analysis is confirmatory, improvements in the patient’s clinical condition can be observed by decrease in work of breathing, good patient-ventilator synchrony, and patient report. If required, EPAP and IPAP can be adjusted by 1 to 2 cm H2O at a time based on the clinical response. If the work of breathing is unchanged, increases in IPAP can reduce hypercarbia by increasing tidal volume and minute ventilation, and increases in EPAP can improve oxygenation by combating atelectasis and promoting alveolar recruitment. IPAP greater than 20 cm H2O should be avoided, because it can be uncomfortable and can cause gastric insufflation.

Mechanical Ventilation of the Intubated Patient

For the intubated patient, initial ventilator settings should facilitate ventilation that improves gas exchange, promotes ventilator synchrony, and minimizes the potential for complications. For an apneic or paralyzed patient, full ventilatory support is required; therefore, A/C is the recommended mode of initial ventilation for emergent patients. Specific required settings depend on whether the patient is receiving PCV or VCV, but the principles underlying the selection of settings are similar. Reasonable initial ventilator settings should deliver a tidal volume of 6 to 8 mL/kg of estimated ideal body weight (IBW) at rate of 12 to 14 breaths/min. If VCV is used, tidal volume can be set directly and, if PCV is used, tidal volume is determined by adjusting the targeted pressure to be delivered. Regardless of VCV or PCV, initial pressure targets should not exceed 30 cm H2O. The initial Fio2 should be set at 1.0 but generally can be adjusted down quickly to maintain an oxygen saturation of 90% or greater. PEEP is routinely given and is set initially at 5 cm H2O. Settings for specific clinical conditions such as status asthmaticus are discussed later.

Ongoing Management

Mechanical ventilation requires monitoring and regular adjustment to ensure appropriate gas exchange, safe delivery of desired tidal volume, and prevention of barotrauma and acid-base
derangement. Changes to ventilator settings are guided dynamically by multiple factors, including pulse oximetry, end-tidal carbon dioxide (ETC\textsubscript{CO\textsubscript{2}}) measurement, ventilation pressures, and blood gas levels. For the adequacy of ventilation to be monitored, capnography must be used, and arterial blood gases should be measured 15 to 20 minutes after the initiation of ventilatory support to correlate ETC\textsubscript{CO\textsubscript{2}} with P\textsubscript{CO\textsubscript{2}}. Notably, venous blood gas levels generally correlate well with the pH of arterial samples, although this correlation may be unreliable in critically ill patients.\textsuperscript{15}

The correlation of P\textsubscript{CO\textsubscript{2}} between venous and arterial samples is less reliable.\textsuperscript{16,17} Although there is variation in agreement between capnography and blood gas values, capnography generally correlates well with the P\textsubscript{CO\textsubscript{2}} of arterial samples and should be used for ventilator adjustment after initial correlation has been established. Recent data have confirmed the importance of continuous capnography, demonstrating a decrease in the use of blood gases and resultant, significant cost savings.\textsuperscript{18} If capnography is difficult to perform or otherwise noncorrelative, arterial blood gas determination remains the definitive test for evaluating \(\text{Pao}_2\) and P\textsubscript{CO\textsubscript{2}}. Minute ventilation can subsequently be altered by adjusting the tidal volume or respiratory rate. To avoid oxygen toxicity, \(\text{FiO}_2\) should be reduced at the earliest opportunity to the lowest level that provides acceptable oxygen saturation (>90%). In many cases, increases in PEEP will allow better oxygenation for a given \(\text{FiO}_2\) but may worsen hypotension or increase intrathoracic pressure.

In addition to maintaining adequate gas exchange, care should be taken to ensure that the pressure in the ventilator circuit (including the lungs) is appropriate. The two main measurements of pressure during mechanical ventilation are the PIP and plateau pressure (P\textsubscript{plat}). The PIP measures the maximum amount of pressure in the ventilator circuit during a breath cycle. It reflects lung compliance and airway resistance, including resistance in the circuit itself. In PCV, because pressure limits are preset, the PIP is the sum of the set pressure target and PEEP. In this case, PIP also reflects the maximum amount of pressure in the alveoli, an important determinant in the development of ventilator-induced lung injury (VILI). In VCV, PIP can be influenced greatly by airway resistance and therefore is not reflective of the maximal alveolar pressure. Rather, maximal alveolar pressure is determined on the ventilator at the end of inspiration by means of an inspiratory hold. At the end of inspiration, flow in the circuit stops; therefore, there is no pressure from resistance in the circuit. P\textsubscript{plat} is measured at that time, so it represents maximal end-inspiratory alveolar pressure in VCV.

Acute increases in measured pressure indicate increased airway resistance or changes in compliance of the respiratory system (eg, those associated with pneumothorax) and can indicate potentially dangerous clinical deterioration. Notably, acute changes in resistance or compliance that are seen directly in VCV as increased pressure would manifest as an acute decrease in tidal volume if the patient were on PCV (where pressure has been previously set). Decreases in lung pressure, conversely, indicate decreased resistance or decreased airflow in the ventilatory circuit and should prompt investigation of the ventilator circuit for leaks. Large or sudden decreases in pressure suggest disconnection of the ventilator circuit or unintended extubation. For patients with underlying respiratory failure secondary to increased airway resistance such as in asthma or COPD, more gradual decreases in PIP are associated with clinical improvement.

### Sedation and Analgesia of the Ventilated Patient

Aside from specific ventilator management, considerations in the care of the intubated patient include analgesia and sedation, potential neuromuscular paralysis, and secretion management. After intubation, the primary goals of care in the ED are sustained, effective ventilation and patient comfort. Intubation, mechanical ventilation, and paralysis are a significant cause of pain and anxiety for patients, and analgesia and sedation are required to promote patient comfort and patient-ventilator synchrony. In initiating sedation (see later), sedation should be titrated to comfort and therapeutic goals, avoiding oversedation and undersedation. The desired level of sedation will differ based on patient tolerance and the clinical scenario; assuming that comfort is maintained, lighter sedation may be useful in patients requiring serial neurologic examinations, whereas deep sedation is required for any patient who is paralyzed. Several clinical scales, including the Richmond Agitation-Sedation Scale (RASS), have been established and validated for this purpose. Sedation should be maintained at the highest RASS score at which the patient is comfortable (between 0 and −5) and should be serially readdressed. Any paralyzed patient should remain deeply sedated (Table 2.3). Recent ED-based data have demonstrated that the use of rocuronium during rapid sequence intubation (RSI) is associated with increased time to adequate sedation, as well as decreased overall dose of sedation, when compared to patients intubated with succinylcholine.\textsuperscript{16,20} This is likely because emergency clinicians wrongly ascribe the patient’s inability to move or respond to adequate sedation, rather than to the paralysis. When rocuronium is used for RSI, additional sedation should be immediately administered after intubation confirmation.

After RSI, additional neuromuscular blocking agents (NMBAs) should generally be used only when poor ventilator synchrony interferes with ventilation sedation and analgesia. This may be particularly true in patients with ARDS, in whom the use of NMBAs has been associated with shorter duration of ventilation and improved mortality.\textsuperscript{21} With proper sedation and analgesia, however, neuromuscular blockade usually is not required.

needed, single doses of longer acting agents such as rocuronium and vecuronium should be used; note that impaired hepatic or renal function may increase duration of paralysis.

Analgesia is achieved by generous doses of opioid medications; fentanyl and morphine remain the most commonly used agents for analgesia in critically ill patients. Opioids are associated with dose-dependent respiratory depression, a side effect that may be particularly beneficial for patients experiencing ventilator dysynchrony. Morphine and fentanyl can be used for analgesia, although dosage requirements will vary based on tolerance and drug metabolism. Sedation and analgesia should therefore be titrated with a standard sedation scale, as discussed earlier. Notably, the active metabolite of morphine (morphine-6-glucuronide) is cleared renally and has potent sedative effects. For this reason, fentanyl may be preferred in patients with renal insufficiency. Remifentanil is an ultra–short-acting opiate that is metabolized by nonspecific plasma esterases. The predictable metabolism and short half-life of remifentanil have made it a choice for analgesia, and studies have demonstrated decreased duration of ventilation with remifentanil compared with longer acting opiates when used for analgesia in the ICU.

Sedation after intubation can be accomplished via multiple pharmacologic modalities. In the ICU, benzodiazepines remain a common choice for sedation, with lorazepam and midazolam being the most commonly used agents. Although data regarding postintubation sedation in the ED are limited, a large retrospective study has found that fewer than 50% of all ED patients received any sedation following RSI in the ED. When sedation was administered, benzodiazepines were the most common agents used.

Benzodiazepines exert dose-dependent clinical effects by binding γ-aminobutyric acid (GABA) receptors, first producing anxiolysis and then sedation and hypnosis. Benzodiazepines also cause respiratory depression, which is potentiated by concomitant opioid administration. Therefore, a sedation regimen of opioids and benzodiazepines may improve ventilator dysynchrony while providing anxiolytic and amnestic effects. Benzodiazepines can be administered as repeated boluses or by continuous infusion although, in critically ill patients, benzodiazepines have altered pharmacokinetics that result in tissue accumulation and prolonged sedation. This is particularly true in obese patients and patients with renal or hepatic insufficiency. For this reason, sedation with benzodiazepines should be attempted with intermittent bolus administration before a continuous infusion is used.

Propofol is lipophilic, and the ability of the drug to penetrate the blood-brain barrier rapidly and distribute into peripheral tissues is responsible for the rapidity and short duration of its clinical effect. Similar to benzodiazepines, propofol binds to the GABA receptor to induce sedation. Unlike benzodiazepines, the clearance of propofol is minimally affected in critically ill patients. In addition, propofol can precipitate hypotension by increasing venous capacitance, a side effect that is exaggerated in hypovolemic patients. Thus, propofol should be given as an infusion rather than as a bolus, initiated at low doses (0.1 mg/kg/min) and titrated to the desired level of sedation. In comparison to benzodiazepines, continuous infusions of propofol have been demonstrated to decrease the duration of mechanical ventilation, suggesting that propofol may confer benefit when compared with benzodiazepines in the sedation regimen for mechanically ventilated patients.

Other medications for the sedation of ventilated patients in the ED include dexmedetomidine and haloperidol. Dexmedetomidine is a centrally acting α2-agonist with sedative and analgesic properties, largely distinguished from other sedative agents by a negligible impact on respiratory drive, even with simultaneous opioid administration. It is administered as a loading dose, followed by a continuous infusion, and can precipitate bradycardia and relative hypertension. Studies have demonstrated dexmedetomidine to be beneficial in facilitating the use of noninvasive ventilation, as well as awake fiberoptic intubations. When dexmedetomidine was compared with a continuous infusion of midazolam, several large, multicenter evaluations demonstrated that dexmedetomidine was associated with a shorter duration of mechanical ventilation, as well as decreased sedation-associated delirium. Although not systematically studied in ventilated ED patients, dexmedetomidine has emerged as an alternative sedation strategy for critically ill patients and may be considered as an alternative to traditional modalities in clinical settings in which agitation or anxiety limit therapeutic goals.

Haloperidol, commonly used as a sedative for agitated patients, can also be used as an adjunct to traditional sedation regimens in mechanically ventilated patients. Haloperidol may be particularly useful for patients who remain acutely agitated after receiving large doses of other sedative medications, especially because it does not affect hemodynamics. Notably, however, haloperidol does not have any analgesic or amnestic properties and cannot be used as a single therapeutic modality for sedation in critically ill patients.

Other ED considerations in the care of the ventilated patient include secretion management and steps to reduce the development of ventilator-associated pneumonia (VAP). Management of secretions is achieved via regular endotracheal suctioning, recognizing a balance between secretion clearance and the disruption of ventilation. In addition, a nasogastric or orogastric tube should be placed for gastrointestinal decompression. Finally, evidence has demonstrated benefit in the prevention of VAP from placing the patient in the semirecumbent position by elevating the head of the bed. Limited data have suggested that the use of so-called VAP care bundles, including elevation of the head of the bed, have decreased the incidence of VAP in the ICU; this may warrant further study to determine benefit in the ED. A meta-analysis has also demonstrated a decrease in the incidence of VAP with continuous aspiration of subglottic secretions. This is done via a specialized endotracheal tube used for this purpose and, although not routinely used in the ED, this technique may be a direction for future investigation.

Complications

Although initiated as a lifesaving intervention, PPV carries the risk of significant complications. As highlighted earlier, the initiation of PPV and elevated intrathoracic pressure can be associated with relative hypotension, and any subsequent changes in end-inspiratory alveolar pressures or PEEP during the management of ventilation may have hemodynamic consequences.

PPV also has a direct impact on the lungs. Whether delivered as a set volume or set pressure, invasive PPV forcibly distends the lung and can be injurious. Injuries from elevated lung volume or lung pressure are known as volutrauma and barotrauma, respectively, and contribute to the development of VILI. VILI is mitigated by limiting pathologic stretch on the alveoli; studies have supported that maximum safe end-inspiratory alveolar pressures are 30 to 32 cm H2O, although this continues to be actively researched. Barotrauma can also manifest overtly with pneumothorax or pneumomediastinum, but this is relatively uncommon.

Another potential complication of PPV is the development of iPEEP (auto-PEEP). Particularly problematic in patients with obstructive lung disease, iPEEP is the accumulation of end-inspiratory volume and end-expiratory pressure that occurs when exhalation cannot be fully completed. In patients with obstructive lung disease, expiratory flow is limited secondary to small airway obstruction and diminished elastic recoil. The time required for full exhalation may be significantly longer than norma, and, in patients receiving mechanical ventilation, exhalation may not be complete before the next delivered breath. This phenomenon,
termed breath stacking, results in dynamic hyperinflation. iPEEP results in unexpectedly high PIPs, difficulty in ventilation, hypotension, and potential circulatory collapse. Ventilation difficulty caused by iPEEP can be improved by decreasing the respiratory rate or inspiratory time, both of which facilitate increased time for exhalation.

**Troubleshooting the Ventilator**

When a patient’s condition suddenly deteriorates during mechanical ventilation, a systematic approach should be applied to assess for life-threatening conditions (Fig. 2.1). The first step in evaluating the ventilated patient who has a change in clinical status is to assess vital signs. Patients with acute hemodynamic compromise or acute hypoxia should be removed from the ventilator and bagged manually on 100% oxygen. Tension pneumothorax, endotracheal tube cuff leak, and patency of the endotracheal tube before other diagnoses are addressed. While the patient is bagged, the chest should be examined to ensure bilateral breath sounds. Changes in breath sounds may indicate a pneumothorax or migration of the endotracheal tube. Clinical examination, oxygen saturation, and EtCO2 monitoring can be used as surrogates for tube placement, but suspicion of inadvertent extubation should prompt direct visualization. Acute hypotension can be precipitated by extreme elevations in intrathoracic pressure; compromise from iPEEP will improve once the patient has been disconnected from the ventilator, whereas hypotension from a tension pneumothorax will not be relieved. If the patient’s condition remains unstable after she or he has been disconnected from the ventilator circuit, a tension pneumothorax should be treated presumptively with needle decompression and eventual chest tube placement. Although unlikely, it is possible that a patient could sustain bilateral pneumothoraces, and this should be considered. If the patient remains unstable after chest decompression, sources for decompensation unrelated to the ventilator are pursued.

Acute distress without hemodynamic changes can be precipitated by multiple factors, mechanical and physiologic (Table 2.4). The initial evaluation should begin by confirming the position and patency of the endotracheal tube before other diagnoses are investigated, including evaluation of the tracheal balloon. Once tube placement has been confirmed, the next step in the evaluation of ventilator-related causes of distress should focus on airway pressures. Acute decreases in PIP indicate discontinuity in the ventilator circuit, which could include inadvertent extubation. Patients with increased PIP can be considered in two categories—those with concomitant increases in Pplat and those with unchanged Pplat. If both PIP and Pplat acutely increase, this suggests decreased compliance of the respiratory system. Elevated PIP with unchanged Pplat indicates problems with increased airway resistance in the lungs or ventilator circuit. Specific conditions that cause decreased respiratory system compliance or increased airway resistance are detailed in Fig. 2.1.
Special Clinical Circumstances

Although generalizations can be made regarding ventilatory management in the ED, certain clinical circumstances merit specific discussion.

Acute Exacerbation of Chronic Obstructive Pulmonary Disease

Strategies for managing intubated patients with COPD focus on improving gas exchange while minimizing iPEEP. Reduction of iPEEP is achieved by decreasing airway resistance with bronchodilators and corticosteroids, as well as ensuring adequate expiratory time during mechanical ventilation. Adequate expiratory time is achieved by decreasing respiratory rate, tidal volume, and inspiratory time. Adequate oxygenation (saturation of 90%) is achieved while minimizing barotrauma by deliberately reducing minute ventilation, so-called permissive hypercapnia. No data have suggested the advantage of PCV over VCV, and either method can be used. The ideal ratio of inspiratory-to-expiratory time (I/E ratio) is variable, but should initially be set at 1:4. Studies in asthmatics have suggested that expiratory times longer than 4 seconds have minimal impact on airflow. iPEEP can also result in poor patient-ventilator synchrony, causing inadequate gas exchange. Unlike in patients with acute asthma (see below), applied PEEP should be used in patients with COPD; it can be set initially at 5 cm H₂O. Initially, deep sedation and analgesia (or sometimes paralytics) are required to prevent ventilator asynchrony and permit effective ventilation. Corticosteroids often are indicated (see Chapter 64). NBMAs are avoided, if possible, because patients receiving both NMBAs and corticosteroids are at higher risk for polymyopathy of critical illness and subsequent increased mortality.

Status Asthmaticus

Concerns in ventilating the acute asthmatic generally parallel those for patients with COPD, with small notable differences. In acute asthma, respiratory failure is a result of airway obstruction and airway inflammation. Furthermore, unlike COPD, airway obstruction is much less dynamic and occurs predominantly in the large airways. In addition, acute inflammatory changes throughout the lung contribute to decreased lung compliance, which has a direct impact on lung pressures during ventilation. Strategies should focus on low respiratory rates, with emphasis on minimizing expiratory time. The use of PEEP has been debated and is largely thought to contribute to increased lung pressure. Although no studies have definitively supported VCV over PCV, decreased lung compliance and potential iPEEP may make the delivery of adequate tidal volumes with PCV difficult. This is especially problematic for patients with severe, acute respiratory acidosis, for whom adequate ventilation is essential. Recommendations for ventilator settings include VCV with tidal volumes of 6 to 8 mL/kg IBW, respiratory rate of 10 to 15 breaths/min, and little (5 cm H₂O) or no PEEP. Decreased inspiratory time allows greater expiratory time and, in VCV, is achieved by increasing the inspiratory flow rate. Increases in inspiratory flow rate, however, will increase airway pressures, emphasizing the interplay of inspiratory time, tidal volume, and airway pressure.

Acute Respiratory Distress Syndrome

ARDS represents a spectrum of inflammatory lung disease characterized by heterogeneous noncardiogenic pulmonary edema, hypoxia, and diffuse lung consolidation. The severity of ARDS is classified as mild, moderate, or severe and is defined by the ratio of arterial oxygen concentration to the fraction of inspired oxygen (Pao₂/Fio₂). Notably, this definition was refined in 2012, and the term acute lung injury was eliminated. ARDS can be caused by pulmonary or extrapulmonary insult, including VILI. Recent epidemiologic data from cohorts of ED patients with sepsis have suggested that although ARDS is uncommon on initial presentation to the ED, the development of ARDS after ED admission is not. The impact of ventilation in the ED on the development of lung injury or ARDS is unclear. Nonetheless, the development of VILI has been associated with lung overdistention and alveolar injury, and attention to ventilation strategy in the ED is warranted. Studies have confirmed that decreased tidal volumes are of clear benefit in the management of patients with ARDS. Most studies examining low tidal volume ventilation strategies, including the landmark ARDSnet trial in 2000, used 6- to 7-mL/kg tidal volumes based on IBW, although studies with 7 mL/kg did not demonstrate a difference in mortality. A meta-analysis of these data has concluded that tidal volumes below 7 mL/kg and Pplat less than 31 cm H₂O confer mortality benefit in patients with ARDS, although more recent work has suggested that low tidal volume ventilation may improve outcome for patients without lung injury as well, including halting progression to ARDS. The level of PEEP in patients with ARDS continues to be actively researched and, although higher levels of PEEP have been demonstrated to improve oxygenation, they have not reduced mortality. Therefore, in patients with ARDS (Pao₂/Fio₂ < 300), a low tidal ventilation strategy should be used. Initial ventilator settings should be volume-cycled, with tidal volumes based on 6 mL/kg of IBW. Although there have been no specific studies examining ventilation strategies for ED patients without evidence of ARDS, studies from other populations have suggested a benefit of lung protective ventilation for all patients; I recommend this strategy for all patients receiving mechanical ventilation in the ED. That said, despite the potential benefit, recent observational data have suggested that adherence to lung-protective ventilation strategies in the ED is just over 50%.

OUTCOMES

Because of the heterogeneity of ventilation strategies and clinical reasons for respiratory failure, no studies have shown the superiority of one ventilation method over another; considerations in initiating mechanical ventilation are individualized and serially reevaluated. Nonetheless, certain conclusions regarding outcomes can be made. Data have clearly indicated the effectiveness of NPPV in preventing intubation for patients with COPD and ACPE, and these benefits have resulted in decreased admission to the ICU and decreased mortality. In addition, increased alveolar volumes and pressures have been shown to contribute to VILI and increase mortality in patients with ARDS. Although the benefit of decreased tidal volume ventilation on the prevention of lung injury in patients with normal lungs has not been proven, emerging data have suggested that strategies of mechanical ventilation in the ED can improve the subsequent clinical course of critically ill patients.

Finally, although the treatment of mechanically ventilated patients usually extends beyond the ED, delays in ICU admission can have significant implications on ED management of the critically ill ventilated patient because the role of emergency clinicians extends beyond acute stabilization toward ongoing clinical management. In addition, when boarding times are long, patients intubated solely for airway protection may be candidates for extubation in the ED if the initial insult has been reversed.
KEY CONCEPTS

- There have been no demonstrated outcomes differences between BiPAP and CPAP. After appropriate patient selections, begin NIPPV with an inspiratory pressure setting of 10 cm of water and expiratory pressure of 5 cm of water and evaluate frequently for tolerance and need to titrate up or down.

- Pressure controlled (PC) ventilation delivers breaths at a predetermined pressure, which might result in low volume delivery, while volume controlled (VC) delivers a predetermined inspiratory volume, which might lead to excessive pressures. Continuous mandatory ventilation (CMV) delivers a required number and volume of breaths per minute while synchronized intermittent-mandatory ventilation (SIMV) synchronizes mandatory breaths with spontaneous breaths.

- Noninvasive ventilatory support is often adequate for reversal of impending respiratory failure and should considered as the first-line therapy for patients with exacerbations of chronic obstructive pulmonary disease and acute cardiogenic pulmonary edema in whom immediate intubation is not required. When non-invasive ventilation is attempted for patients with pneumonia, it should be abandoned in favor of intubation with mechanical positive-pressure ventilation unless the patient is clearly improving. Prolonged use of non-invasive ventilation that ultimately fails is associated with worse outcomes for patients than when intubation is undertaken earlier.

- Invasive mechanical ventilation is not without consequence and requires dynamic, ongoing management. After intubation, blood gas analysis should be performed to confirm appropriate ventilation and provide correlation with noninvasive monitoring of oxyhemoglobin saturation and end-tidal CO2. In addition, positive pressure can have adverse hemodynamic consequences. Elevated lung pressures can be deleterious and plateau pressure should be maintained below 30 cm H2O whenever possible, by adjusting ventilator settings. Progressive elevation in ventilation pressures prompts consideration of ventilator circuit obstruction, obstruction at any point of the airway, increased bronchospasm, mainstem intubation, tension pneumothorax or hemothorax, increased chest wall resistance (from a constricting device or intrinsic chest wall), or rigidity (as from high doses of fentanyl). Suddenly reduced ventilation pressures are often accompanied by increasing hypoxemia and indicate ventilator circuit leak or faulty connection, endotracheal tube cuff leak, accidental extubation, or esophageal intubation.

- The Richmond Agitation Sedation Score (RASS) or a similar scoring system should be used to manage sedation and analgesia of the mechanically ventilated patient to avoid unnecessary use of prolonged neuromuscular blockade. When RASS is used, a target score of -2 to 0 avoids both over and under sedation.

CHAPTER 2: QUESTIONS & ANSWERS

2.1. Which of the following is the most important consideration in the decision to initiate noninvasive positive-pressure ventilation (NPPV)?

A. Degree of acicosis
B. Degree of respiratory distress
C. Hemodynamic profile
D. Level of consciousness
E. Underlying etiology of respiratory failure

Answer: B. Although NPPV will be helpful for many patients in distress, the need for emergent intubation is an absolute contraindication to NPPV. Both hemodynamic profile and level of consciousness are important determinants in the decision to implement NPPV, but both are relative (rather than absolute) contraindications to its use. Patients with chronic obstructive pulmonary disease (COPD), acute cardiogenic pulmonary edema (ACPE), and asthma are more likely to show benefit with NPPV than patients with pneumonia, but NPPV can be initiated for any patient with respiratory distress. Patients with hypoxia or hypercarbia may be acidic, but the decision to initiate NPPV will be predicated on mental status and work of breathing rather than on degree of acidosisis alone.

2.2. Which of the following is a potential adverse effect of positive-pressure ventilation?

A. Decreased mean intrathoracic pressure
B. Decreased ventilation/perfusion ratio
C. Increased cardiac output
D. Increased glomerular filtration rate
E. Increased work of breathing

Answer: E. Positive-pressure ventilation (PPV) is associated with several complications. Some of these can quickly become life-threatening. This reality underscores the importance of familiarization with the common problems that arise as a result of PPV. Most complications result from changes in thoracic physiology
when positive pressure is present for part or all of the respiratory cycle. Potential adverse effects of PPV include an increased work of breathing because of asynchrony or improperly set triggers, an increase in intrathoracic pressure, decreased venous return to the heart and decreased cardiac output, an increased ventilation/perfusion ratio, air trapping and intrinsic positive end-expiratory pressure, barotrauma, decreased renal blood flow and glomerular filtration rate with fluid retention, nosocomial infections of the lungs and sinuses, respiratory alkalosis, and agitation and increased respiratory distress.

2.3. What is the primary physiologic effect of applying positive end-expiratory pressure (PEEP) during mechanical ventilation?

A. Decrease cardiac output
B. Decrease intrapulmonary shunting
C. Decrease ventilation/perfusion mismatch
D. Increase functional residual capacity
E. Increase partial pressure of oxygen (\(P_{aO_2}\))

**Answer:** D. Although all of these effects can be attributed to the application of PEEP, its primary physiologic effect is to increase functional residual capacity (FRC) by maintaining patency of injured or flooded alveoli that would otherwise collapse at the end of exhalation. Increasing the FRC may improve both oxygenation and lung compliance. PEEP increases \(P_{aO_2}\) at a constant fraction of inspired oxygen (\(F_{iO_2}\)) by decreasing intrapulmonary shunting and ventilation/perfusion mismatch. One of the potential adverse effects to PEEP is decreased cardiac output.

2.4. Regarding a patient who develops acute distress on mechanical ventilation, which of the following is the most accurate?

A. Accidental extubation is a common cause of increased airway pressure.
B. Anaphylaxis would cause immediate increases in both peak inspiratory pressure (PIP) and plateau pressure (Pplat).
C. All patients in distress should be immediately removed from the ventilator and bagged.
D. Compared to patients with restrictive lung disease, patients with obstructive lung disease are more likely to decompensate because of inappropriately set respiratory rate.
E. Presumptive needle thoracostomy is indicated for all hemodynamically unstable patients.

**Answer:** D. One of the most life-threatening complications of mechanical ventilation is loss of adequate cardiac output because of elevated intrathoracic pressure from intrinsic PEEP (iPEEP). Intrinsic PEEP can be precipitated by a respiratory rate that is too high, which does not allow patients to fully exhale before the delivery of another breath. Patients with obstructive lung disease such as COPD or acute asthma are particularly sensitive to this phenomenon, also known as “breath stacking.” Although patients with restrictive lung disease may develop iPEEP with an inappropriate respiratory rate, this is much more likely to occur in patients with obstructive conditions. If patients are not hemodynamically unstable, they do not need to be removed from the ventilator, and in hemodynamically unstable patients, pneumothorax should only be presumptively treated if removing the patient from the ventilator does not improve the situation. Accidental extubation is a common cause of decreased airway pressures, and although anaphylaxis would cause increases in PIP, it would not typically cause increases in Pplat.
CHAPTER 3

Pain Management

James R. Miner | John H. Burton

PRINCIPLES

Background and Importance

Pain-related complaints represent the primary cause of concern in as many as 70% of patients presenting to the emergency department (ED) setting. Uncontrolled pain should be considered a medical emergency. The estimated degree of pain experienced by a patient should play a role in the determination of a patient’s overall acuity and urgency for therapy. Pain estimations, using both provider- and patient-derived scales, should be obtained and recorded to determine not only the presence of pain but the response to pain therapy. Although pain can be present in a wide variety of physical and psychosocial situations, it is typically present in the context of tissue injury. Pain can therefore be assumed to be present in patients with physically apparent disease or injury, even in those who cannot effectively communicate their condition. Important terms relating to analgesic practices are listed in Box 3.1.

A wide variety of options are available for the effective treatment of pain. Despite having treatments available for acute and chronic pain therapy, the treatment of pain can be difficult and is often one of the most challenging and frustrating aspects of the practice of emergency medicine.

Patients’ perceptions of their ED care are highly influenced by pain treatment. Satisfaction with emergency care often depends on the techniques and timeliness of analgesia, as well as the discharge plans for pain relief. In every interaction with a patient in pain, a balance must be achieved between relief of patient suffering and the diagnosis and treatment of the underlying medical condition.

A growing body of evidence has supported the importance of pain management as a central aspect for disease treatment. Unrelied pain is associated with a variety of potentially negative physiologic outcomes, including increases in sympathetic outflow, peripheral vascular resistance, myocardial oxygen consumption, and the production of carbon dioxide. Other adverse effects of unrelied pain include hypercoagulability, decreases in gastric motility, and immune function impairment. Poorly treated acute pain can promote the development of chronic pain syndromes and vegetative symptoms, as well as increase the need for pain management during any recovery period. Pain during serial medical procedures may increase if successful analgesia was not provided during initial procedures. It is also likely that a patient’s experience of pain increases his or her ability to perceive pain from similar stimuli in the future.

As an affirmation of the recognized importance of pain management in health care, the Center for Medicare and Medicaid Services and The Joint Commission for accreditation of health care organizations require hospitals to develop quality improvement efforts related to acute pain management, in addition to comprehensive programs for the measurement, documentation, and treatment of pain.

Anatomy, Physiology, and Pathophysiology

Pain can be generally described by the terms nociceptive and neuropathic. Nociceptive pain results from the activation of sensory neurons that signal pain (nociceptors) in response to noxious stimuli. Neuropathic pain results from signal-processing changes in the central nervous system (CNS). Neuropathic pain is usually described as burning, tingling, or shooting sensations, and includes neuropathies and deafferentiation. Both nociceptive and neuropathic pains involve peripheral and central sensitization with a complex array of mediators to sensitize peripheral nociceptors and perpetuate thalamic signals (Fig. 3.1). At each level in the physiologic process of pain production or transmission, interventions and therapeutic opportunities should be considered to alter the process with a goal of improving the patient’s pain experience.

Pain Conduction Pathways

Pain perception can be divided into four separate processes (see Fig. 3.1): pain detection (transduction), pain transmission, pain modulation, and pain expression (perception).

Pain Detection

The somatosensory system is responsible for the detection of pain as well as tactile, proprioceptive, and thermal sensations. Receptors responsible for the detection of pain are termed nociceptors. Nociceptors include sensory nerves that are capable of detecting mechanical, thermal, or chemical stimulation. Several different subtypes of nociceptors are present in cutaneous tissues, including mechanoreceptors, polymodal nociceptors (PMNs), and a variety of thermoreceptors.

The threshold of activation of a nociceptor can be modulated—increased or decreased—by a variety of chemical mediators, including prostaglandin, cyclic adenosine monophosphate, leukotrienes, bradykinins, serotonin, substance P, thromboxanes, platelet-activating factor, and endorphins. This change in nociceptor activation thresholds is termed peripheral sensitization. Trigger points, for example, are areas of frequent or constant low-level sensory stimulation (eg, scar tissue or a degenerative joint) that have developed peripheral sensitized nociceptors that perceive pain from otherwise innocuous stimuli.

Information Transmission

Peripheral Nerve Fibers. All sensory neurons are composed of a cell body located in the dorsal root ganglia. The dorsal root ganglia are connected by nerve axon fibers with sensory receptors located in a number of body sites, including dermatomes (cutaneous input), sclerotomes (input from bones), and myotomes (input from muscle). The discrete areas covered by each nerve provide a sensory map of the body surface.
Peripheral nerve fibers can be classified by the roles of each fiber group (Table 3.1). A-δ and C fibers fibers are responsible for the transmission of pain. A-δ fibers transmit sharp, initial pain; C fibers, in contrast, transmit dull, aching, or burning pain. The pain transmitted by A-δ fibers persists only as long as the initial stimulus is in effect, whereas C fiber pain persists longer than the initial stimuli, rendering a prolonged pain sensory experience. The relative concentration of nerve fiber types, both C and A-δ varies by body tissue.

**Pain Transmission**

**Dorsal Horn.** The dorsal horn is the gray matter of the posterior aspect of the spinal cord (Fig. 3.2). The dorsal horn acts as an integration system in which sensory input is filtered, attenuated, or amplified before being relayed to other spinal segments or the cortex.

The dorsal horn is a processing center for incoming information and is extensively involved in the modulation of nociceptive input. Afferents from visceral, muscle, bone, and cutaneous areas converge in the dorsal horn and likely account for the cutaneous transmissions associated with painful visceral, muscular, or bony stimuli.

Differentiation between innocuous stimuli and nociceptor input occurs in the dorsal horn by stimuli received in cells referred to as wide dynamic range neurons (WDRNs). WDRNs receive modulating input from a variety of chemical pathways, such as opioids, substance P, or inflammatory factors. These cells also receive modulating input from efferent and afferent neuronal pathways.

**Visceral Pain.** The quantity and type of stimuli that produce pain varies among visceral structures. The myocardium, for example, is sensitive to ischemia but not mechanical stimulation. Tissues in the intestine may be severed, crushed, or burned without pain; however, traction or distention produces pain sensations in this area.

The quality of visceral pain is unique from somatic pain. Somatic pain is initially sharp, later becoming burning or throb- ing in nature as the response is modulated. In contrast, visceral pain tends to start as poorly localized, dull, and aching, with pronounced autonomic activation. These sensations may then

**BOX 3.1**

**Definitions of Terms Related to Analgesia**

- Allodynia—pain from a stimulus that does not normally provoke pain
- Amnestic—an agent that suppresses the formation of memories
- Local anesthesia—creates an area of insensibility to pain by injection of a local anesthetic agent
- Analgesia—relief from pain
- Hypnotic—agent that promotes the onset of sleep
- Narcotic—term with legal implications describing opioid agents together with various central nervous system depressant drugs of abuse
- Nociceptor—receptor that is sensitive and responsible for transmitting pain stimuli
- Noxious stimulus—stimulus that is damaging or potentially damaging and results in sensation of pain
- Opiate—naturally occurring derivative of opium alkaloid that binds opiate receptors and produces effects similar to those of the endogenous endorphins
- Opioid—naturally occurring or semisynthetic derivative of opium alkaloid (includes all opiates) that binds opiate receptors and produces effects similar to those of endogenous endorphins
- Pain—unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage
- Procedural sedation—pharmacologic induction of a state of sedation or dissociation with amnesia for pain control during a painful procedure
- Sedative—agent that decreases a patient’s level of awareness

Spinal

PART I

Fundamental Clinical Concepts

SECTION ONE

Critical Management Principles

develop into sharp, localized, referred pain. This progression is likely due to the varying ratios of A to C fibers, which are 1:10 in visceral nerves and 1:2 in cutaneous nerves.

Visceral pain often produces referred pain. For example, periumbilical pain is often associated with appendicitis. This referred pain sensation occurs due to visceral afferents supplying the small bowel and traveling through the celiac ganglia and splanchic nerves to enter the spinal cord at T10. This input sensitizes the dorsal horn at T10, leading to sensitization of all the dorsal horn nociceptive neurons and ultimately leading to the perception of pain in the T10 dermatome. As appendicitis progresses, the pain localizes to the right lower quadrant as inflammation extends to the parietal peritoneum with the same nerve supply as the overlying dermatome.

Ascending Tracts Associated With Pain. Fibers carrying pain impulses exit the dorsal horn and ascend the spinal cord to the brain. The predominant pathways for pain conduction through the spinal cord are the spinothalamic, spinomesencephalic, and spinoreticular tracts, located in the anterolateral aspect of the spinal cord (Fig. 3.3; see Fig. 3.2).

Pain Modulation

Impulses from nociceptors are modulated by descending tracts in the spinal cord. The two primary descending pathways appear to be serotonergic and noradrenergic. These pathways originate in the midbrain (periaqueductal gray matter and locus ceruleus) and medulla (nucleus raphe magnus and nucleus reticularis gigantocellularis) and are transmitted to the spinal cord via the dorsolateral funiculus.

Electrical stimulation of descending pathways produces analgesia comparable to that produced with opioids. Stimulation of the thalamus can also produce analgesia. Inputs to this system come from the frontal cortex, limbic system, hypothalamus, reticular system, locus ceruleus, and spinal cord. Multiple neurotransmitters are involved in these pathways, including serotonin, norepinephrine, and substance P. It is believed that the activation of this system is responsible for effects such as placebo, acupuncture, and transcutaneous electrical nerve stimulation (TENS) units, as well as stress-associated pain tolerance.

Central Sensitization

Central sensitization involves the amplification of nociceptive signals. Central sensitization is mediated by a number of substances, such as nitric oxide, glutamate, substance P, aspartate, prostaglandins, leukotrienes, norepinephrine, and serotonin. It can occur in the presence of chronic pain or can be the result of damage at any point along the pain transmission system. Central sensitization is described in the setting of traumatic and degenerative conditions of the spinal cord and brainstem and can be associated with thalamic strokes, multiple sclerosis, Parkinson’s disease, Arnold-Chiari formation, and cervical stenosis.

Pain Expression

The transduction, transmission, and modulation of pain stimuli develop the perception of the subjective emotional experience of pain. Many factors other than the stimulation of nociceptors influence the final perception of pain. The discrete cognitive processes and pathways involved in the interpretation and experience of painful stimuli still remain a mystery and are affected by factors such as cultural expectations, personality, experiences, and underlying emotional state. Many of these factors, and therefore

![Fig. 3.2. Spinal tracts.](https://t.me/ebookers)

![Fig. 3.3. Spinal cord.](https://t.me/ebookers)
the subsequent perception of pain, can be greatly influenced by pharmacologic and nonpharmacologic interventions.

For drugs such as nitrous oxide and low-dose opioids, much of their analgesic effect is on the cognitive interpretation and emotional reaction to pain rather than on transmission of the pain stimulus. Noninvasive techniques (eg, distraction, hypnosis) can limit pain perceptions and increase tolerance. Changes how a person experiences pain, based on previous experiences and learned behaviors, are referred to as cognitive sensitization.

**Reflex Responses to Pain**

There are two types of reflex responses to nociceptor input, spinal segmental (or suprasegmental) and cortical. Spinal reflexes are generated by the transmission of nociceptive impulses from the dorsal horn to motor and autonomic neurons in the spinal cord, provoking a range of responses, including tachycardia, vasoconstriction, paralytic ileus, and muscle spasm (Box 3.2). Suprasegmental reflexes are transmitted through ascending tracts to the brainstem, hypothalamus, and cortex, where withdrawal reflexes and autonomic responses occur in connection with conscious responses. The autonomic reflex responses to pain are variable and cannot be used to quantify pain in an individual.

**Endorphin System**

The endorphin system is a neuroendocrine system that serves to modulate responses to pain and stress. The endorphin system consists of widely scattered neurons that produce three types of opioids—beta-endorphin, met- and leu-enkephalins, and dynorphins. These opioids act as neurotransmitters and neuromodulators at three major classes of receptors—mu, delta, and kappa—and produce analgesia as well as counter the stress response (Table 3.2).

Under normal circumstances, the endorphin system serves to decrease pain and stress after a person has adequately dealt with the inciting noxious stimuli. The endorphin system normally is a responsive system that can have an increased or decreased effect to produce the appropriate response to a painful event. Like other neuroendocrine systems, increasing stimulation by endorphins produces feedback inhibition on their own circulating levels. During prolonged periods of pain with high levels of stimulation, the system can become less responsive and less effective at modulating the pain response.

Like their endogenous counterparts, opiates act at chemical receptors to produce analgesia and undesirable side effects. As these drugs are given over a prolonged period, they inhibit the endogenous endorphin system, blunting the response to pain and stress and decreasing the overall endorphin effect. As these drugs are withdrawn, the normal effects of the endorphin system resume.

**Acute Versus Chronic Pain**

Acute pain is usually associated with an identifiable pathologic condition and serves an adaptive function by warning the individual that an illness or injury exists. This sequence will motivate the person to cease activity that is causing the pain, look for a cause, seek help, and avoid the stimulus in the future.

Acute pain becomes chronic pain when the pain pattern persists, in changed or unchanged form, after the original physiologic insult has apparently resolved. All chronic pain starts as acute pain, but only small subsets of patients with acute pain develop chronic pain (Table 3.3). The physiologic transition from acute to chronic pain is a complex process, with physiologic and psychosocial components. In many cases, the development of chronic pain is likely related to the treatment of acute pain.

Acute pain serves an important purpose in that it stimulates a person to protect the injured area and seek help. Also, the neurochemical factors that contribute to acute pain acknowledgment will generally initiate and support recruitment of tissue repair mechanisms. As an injury heals, these adaptive responses may become maladaptive if the pain persists because this cycle can lead to a decreased range of motion, decreased function of the area and, ultimately, an increased susceptibility to injury and pain. Pain also causes a stress response that is initially adaptive in the face of injury. A prolonged stress response, however, causes an impaired immune system, hypercoagulable state, sleep disturbances, anxiety, and depression.

### BOX 3.2

**Reflex Responses to Pain**

**INCREASED SYMPTOMATIC TONE**
- Vasodilation producing increased peripheral resistance
- Increased cardiac output from increased stroke volume and heart rate
- Increased blood pressure
- Increased metabolic rate and oxygen consumption
- Decreased gastric tone and gastric emptying (may progress to ileus)
- Decreased urinary tract tone (may lead to urinary retention)

**ENDOCRINE RESPONSES**
- Decreased insulin production
- Increased cortisol levels
- Increased antidiuretic hormone levels
- Increased growth hormone levels
- Increased renin, angiotensin II, aldosterone levels
- Increased glucagon levels
- Increased catecholamine levels

**RESPIRATORY RESPONSES**
- Hyperventilation

**CORTICAL RESPONSES**
- Anxiety and fear

CV, Cardiovascular; GI, gastrointestinal.
The ability to assess pain effectively. Communication between patients and emergency clinicians, communication with the patient—verbal and nonverbal. Barriers to with the degree of pain present. Because pain cannot be objectively index to measure pain reliably. Objective observations, such as information. Unfortunately, there is no objective test or physiologic emergency clinician and the emergency clinician’s ability to obtain this communicate the nature of the painful experience to the emer - injury.

Oligoanalgesia

Because effective treatment is based on the assessment of pain, patients who have difficulty communicating are at particular risk of undertreatment of their pain (oligoanalgesia). Groups at particular risk for oligoanalgesia include infants and children, patients whose cultural and linguistic background differs significantly from the treating emergency clinician, and patients who are developmentally delayed, cognitively impaired, under severe emotional stress, or mentally ill.

There are a variety of reasons why patients do not receive adequate analgesia from health care providers. These include the ineffective assessment of pain, misconceptions about the safety and efficacy of various treatments, and the effect of analgesic interventions on a patient’s evaluation. In the ED, there may be a significant delay to providing adequate pain control. Additionally, when opioids are used, they are often given in subtherapeutic doses.

Pain Measurement

The use of numeric rating scales, using a verbal 0 to 10 score (none to worst imaginable), are ubiquitous in the ED and other settings, where acute pain is managed or invoked (Fig. 3.4). Visual analogue scales, usually consisting of a 10-cm straight line with anchors at either extreme, are frequently used in research to provide continuous data for analysis. These scales offer little practical advantage over verbal reports in the clinical setting. Routine verbal or visual pain scale assessment encourages emergency clinicians to communicate with patients to assess their pain and to evaluate responses to analgesic intervention attempts.

Children require alternative communication techniques to acknowledge and relate pain. The FACES pain scales are designed for children younger than 7 years. This scale has a series of cartoon faces expressing a range of emotions, from happiness to severe distress. The child is asked to point to the face that corresponds to how he or she feels. The FACES pain scale, and others like them, require less of an abstract reference than numeric and verbal scales and are useful in pain assessment for toddlers and cognitively impaired adults.

In preverbal children, observer-derived scales may be used. These include scales such as the Modified Pre-Verbal, Early Verbal Pediatric Pain Scale (M-PEPPS), Children’s Hospital of Eastern Ontario Pain Scale (CHEOPS), and CRIES scale for neonates. These scales use a scoring system for observed criteria that is reproducible among trained observers, making them useful for research. These scales appear to have little clinical utility compared to the emergency clinician’s or parents’ overall impression of the child’s pain.

Pain scores have gained acceptance as the most accurate and reliable measure of assessing a patient’s pain and response to pain treatment. Pain treatment should be targeted to a goal of reducing the pain score (eg, by 50%, below 4/10, or referred to as mild/moderate or severe) rather than a specific (maximum) analgesic dose.

Treatment Groups

The approach to patients in pain should begin with a characteriza -tion of pain patients into four unique treatment groups: (1) chronic pain; (2) recurrent pain; (3) chronic pain of malignancy and neuropathic pain; and (4) acute pain. Therapy for groups other than those with acute pain should focus on a long-term, multidisciplinary approach that includes the emergency clinician and ED as part of a patient’s ongoing comprehensive strategy (Box 3.3). Acute and chronic pain patients have different physiologic

Chronic pain is very common. A large number of patients with chronic pain are seen in the ED. It can be difficult to determine the point at which an adaptive pain response becomes maladaptive, and the progression from acute pain to chronic pain occurs.
Pain a,b obtained pain therapy or pain relief. These behaviors, combined providers are developed around the patient's expectations for 
ior s such as exaggerating symptoms or attempting to manipulate 
with emergency clinicians to receive pain treatment. Many behav-
and others maladaptive, in describing their pain and interacting 
patients with chronic pain develop experiences, some adaptive 
skill on the part of the emergency clinician and patient. Many 
or obvious physical injury requires a great deal of communication

causes and thus require different treatment approaches based on 
their specific site and mechanism of affect (Fig. 3.5).

Chronic Pain. The assessment of pain in the absence of acute 
or obvious physical injury requires a great deal of communication 
skill on the part of the emergency clinician and patient. Many 
patients with chronic pain develop experiences, some adaptive 
and others maladaptive, in describing their pain and interacting 
with emergency clinicians to receive pain treatment. Many behavior s 
such as exaggerating symptoms or attempting to manipulate 
providers are developed around the patient's expectations for 
 obtaining pain therapy or pain relief. These behaviors, combined 
with the negative psychosocial effects and sense of futility associ-
ated with chronic pain, can complicate the evaluation process and 
care of chronic pain patients.

The assessment of chronic pain can represent some of the most 
challenging situations to obtain an accurate clinical history. 
Patients who are having a difficult time describing their pain 
should be encouraged with detailed questions about the pain, 
combined with multiple examples, comparisons, and summariz-
ing statements, to facilitate accurate communication. Assuring 
the patient that the questions are intended to aid understanding 
and enable treatment of symptoms as effectively as possible can fa-
cilitate the development of a common goal and help establish the 
trust necessary to develop an effective treatment strategy.

Patients with chronic pain can present with an exacerbation of 
their chronic pain in the setting of ongoing therapy or with 
untreated chronic pain due to a gap or lack of chronic care. These 
scenarios require different treatment approaches. For chronic 
pain patients with an exacerbation in their pain exceeding the pain 
control of their usual treatment strategy, treatment can be 
approached in a fashion similar to that for acute pain. The goal 
for these patients should be to control the exacerbation and return 
the patient to baseline function.

Many patients with chronic pain are in comprehensive treat-
ment programs, most of which involve a so-called contract with 
respect to the provision of their pain management. For such 
patients, a review of the pain management plan in the medical 
records, or contact with the health care provider who typically 
manages the patient's treatment plan, is a critical element in 
determining the best short-term strategy in the ED.

Patients with chronic pain who have a gap in their baseline 
treatment or who have never established appropriate treatment 
for chronic pain require an approach that addresses the need for 
establishment of a chronic, consistent treatment plan. Patients 
with no ongoing treatment plan should have a basic chronic pain 
treatment plan implemented during their ED visit. This should 
consist of acetaminophen, if not contraindicated, and a nonste-
roidal antiinflammatory drug (NSAID), if tolerated. Tramadol 
may be helpful in certain cases. Adjuvants appropriate for neu-
ropathic or central pain may be added, if appropriate. Opioids for 
chronic pain, whether for a patient already on a treatment plan

Fig. 3.4 Pain scales.
or without a treatment plan, rarely are indicated in the ED care of the chronic pain patient, with the exception of patients who are in care for pain related to advanced malignancy (see below.) Opioids should neither be administered nor prescribed unless their need is verified with the clinician responsible for the patient’s chronic pain management plan. In general, opioids for chronic pain management are the domain of providers in ambulatory pain centers or primary care physicians who will follow the patient’s therapy, response, and compliance. There is often difficulty communicating with the patient, who may have received opioids at many EDs, including the one currently being visited; establishment of a departmental policy empowers emergency clinicians to administer or prescribe opioids for chronic pain syndromes, without judging the patient.

Recurrent Pain. Recurrent pain is a subset of chronic pain; the term describes patients who have symptoms with repeated episodes of similar pain. Recurrent pain can include such disorders as back pain, myofascial pain syndrome, migraine syndrome, sickle cell disease, and inflammatory bowel disease. The approach to the treatment of recurrent pain in the ED incorporates elements of the treatment of acute pain and of chronic pain, and prevention of recurrent pain events must be considered as part of the treatment strategy. These therapies may integrate nonpharmacologic approaches, such as physical therapy for back pain, in addition to the use of preventive medications.

Chronic Pain of Malignancy. Chronic pain due to malignancy is approached differently from other causes of chronic pain. Chronic malignant pain is similar to acute pain in its relation to ongoing nociceptive stimulation and similar to chronic pain in its duration and psychobehavioral effects. The medications used, for the most part, are similar to those used for acute pain. Psychosocial effects of the pain of malignancy must be addressed as part of an effective treatment strategy.

Patients with a significant change in the pattern of their chronic pain caused by cancer or a terminal illness, as with other chronic pain patients, should be evaluated for a new process to account for the pain. Opioids, especially in long-acting or transdermal preparations, should be used liberally to bring pain relief for patients with terminal illnesses.

Neuropathic Pain. Complex regional pain syndrome (CRPS) is a term that includes most sympathetically maintained neuropathic pain. CRPS type 1 (often referred to as reflex sympathetic dystrophy) develops after an injury and typically follows the distribution of a peripheral nerve. It is associated with hyperalgesia, allodynia, changes in skin blood flow, and sympathetic dysfunction. This syndrome develops during the healing and recovery phases of acute painful injuries and is generally described as a burning, tingling sensation in the area of the previous injury, but not in a specific nerve distribution; it is likely related to ongoing painful stimulation leading to the development of self-sustaining modulation of the pain transmission system. CRPS type 2, commonly referred to as causalgia, is associated with burning pain and allodynia in the distribution of an injured nerve, with no association with sympathetic symptoms. Opioids are ineffective in preventing CRPS after an injury has occurred. Clonidine, N-methyl-d-aspartate receptor antagonists, and γ-aminobutyric acid (emergency clinician) receptor agonists are more effective in the treatment of CRPS than opioids. Gabapentin is generally considered a first-line agent, with pregabalin used for patients who cannot tolerate its sedating effects.

Antidepressants have effects on neuropathic pain that appear to be distinct from mood effects. For patients with chronic pain thought to be unrelated to central or neuropathic origins, other antidepressants, such as selective serotonin reuptake inhibitors, may be safer and more effective.

Several anticonvulsants, including gabapentin, phenytoin, carbamazepine, and valproic acid, are described for neuropathic pain with lancinating or burning properties. Carbamazepine is used most frequently for trigeminal neuralgia, postherpetic neuralgia, and diabetic neuropathy. Gabapentin is described for both types of CRPS, postherpetic neuralgia, and diabetic neuropathy.

Acute Pain. Symptomatic treatment of pain should be initiated promptly, titrated to an acceptable level of relief, and continued while the investigation for a cause is proceeding.
The safety of the short-term use of opioids for acute pain, in terms of adequate dosing and excessively infrequent dosing intervals, presents a common approach to acute pain in the ED setting, beginning at triage with the assessment of pain type and severity and then progressing to clinical assessment, with therapeutic suggestions.

When the cause of acute pain is uncertain, immediate relief of pain occurs in parallel with initial efforts to establish the diagnosis. It is inappropriate to delay analgesic use until a diagnosis has been made. There is no evidence that the administration of adequate doses of opioid analgesia to establish patient comfort impairs the emergency clinician’s ability to diagnose the cause of an acutely painful condition. On the contrary, the administration of analgesia may enhance the accuracy of the physical examination and patient assessment.

**Pharmacologic Therapy**

**Opioid Analgesic Agents**

In 1680, Sydenham wrote that “Among the remedies it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium.” Centuries later, this statement is still accurate, with titrated opioids considered to be the therapeutic foundation for severe acute pain.

The beneficial effects of opioids have been well documented for centuries, as have their toxicity and potential for abuse. Unfortunately, opioids are often poorly used in clinical practice. Concerns regarding opioid toxicity or dependence and a poor understanding of the pharmacokinetics of the drugs have led to inadequate dosing and excessively infrequent dosing intervals. The safety of the short-term use of opioids for acute pain, in terms of toxicity and likelihood of causing future dependence, is established. Opioids are the first-line agents in the management of acute severe pain (Table 3.4). This safety is not well established in relation to the treatment of mild or moderate pain, however. The effectiveness of opioids relative to that of nonopioid analgesics, and a similar comparison of potential adverse effects, including the potential for abuse, argues against their use in mild pain and for sharp limits on their use for moderate pain. To prevent the overuse and misuse of opioids, the quantity and strength of the opioids prescribed should closely match the anticipated duration of the severe pain, and the patient should be transitioned off the opioid analgesia at the earliest appropriate opportunity. For most short-term acute pain episodes, such as a fracture, 3 to 5 days of opioid analgesia is sufficient, pending outpatient follow-up evaluation.

**Mechanism of Action and Toxic Effects.** Opioids bind to specific endorphin system receptors located throughout the nervous system. These receptors suppress pain detection peripherally, modify pain transmission in the spinal cord and thalamus, and alter pain perception at the level of the cortex. A variety of endorphin receptors are defined (see Table 3.2). The unique actions of opioids are determined by the specific binding properties of the agent to the various receptors.

Side effects can limit the success of opioid therapy, particularly in the acute treatment setting. The occurrence of side effects varies among individual patients and opioid agents. Tolerance of many side effects develops shortly after the initiation of therapy.

The most common side effect of opioids is constipation. Constipation is attributed to opiate binding of receptors located in the antrum of the stomach and proximal small bowel. Constipation can be anticipated with long-term opioid use (more than a few days). An active laxative, such as senna, lactulose, or bisacodyl, should be prescribed, as needed.

Nausea and vomiting can occur with the administration of opioids, especially in opioid-naïve patients. It is often difficult to distinguish whether nausea and vomiting are caused by the opioid or the acute pain for which it is administered. Routine coadministration of an antiemetic with the opioid, once an almost universal practice, is not necessary. Nausea and vomiting in the context of persistent acute pain after opioid administration may require an additional opioid and antiemetic, such as promethazine, prochlorperazine, or ondansetron.

Immunoglobulin-mediated allergies are rare for morphine and other opioids. Many patients will experience mild pruritus of the trunk and face after parenteral administration. This side effect is related to histamine release from opioid receptors on mast cells and does not constitute an allergy. To a varying degree, opioids destabilize mast cells in a dose-dependent fashion, causing histamine release and resultant urticaria, pruritus, and orthostatic hypotension. This reaction may appear as localized urticaria tracking up a vein after intravenous (IV) administration of an opioid, especially morphine. Rarely, bronchospasm may be seen in patients with reactive airway disease or atopy. This effect usually subsides rapidly, with no treatment required, although the symptoms can be controlled with the administration of an antihistamine.

Sedation and respiratory depression can occur with opioid administration for acute pain. Opioids decrease medullary sensitivity to carbon dioxide, resulting in respiratory depression. The combination of opioids with other sedating agents, such as benzodiazepines, will increase the likelihood of respiratory depression. Patients with underlying hepatic or renal dysfunction are at increased risk because of their inability to clear opiates normally, resulting in the accumulation of active metabolites and a higher risk for sedation or respiratory depression.

Pain is a very effective stimulant of respiratory drive, rendering respiratory depression rare in the context of acute severe pain. Fear of respiratory depression should not deter the emergency clinician from treating pain adequately, although monitoring patients receiving significant doses of narcotics is advised. It should be noted that patients who had previously tolerated a dose of an opioid may develop respiratory depression if the source of acute pain is removed, such as by local anesthesia or the reduction and stabilization of a fracture. Transient respiratory depression
from opioids usually responds to simple verbal or tactile stimulation and, uncommonly, requires more aggressive interventions.

Tolerance and physical dependence are common effects of the prolonged use of opioids. Physical dependence is defined as the occurrence of an opioid withdrawal syndrome following abrupt cessation, rapid dose reduction, or administration of an antagonist. Tolerance is a phenomenon that occurs after prolonged exposure to opioids and is characterized by the diminution of an opioid’s effect over time. Normal expected results of the prolonged use of opioids should be accounted for in planning their use for extended periods and do not represent addiction. Patients who require prolonged treatment with opioids (>5–10 days with regular dosing) will require tapering doses as their painful condition improves to prevent withdrawal. Neglecting to address this issue early in a patient’s treatment can lead to difficulties with safe and tolerable treatment termination.

Addiction is a potential risk associated with prolonged opioid use and often limits use. The term addiction refers to a neurobiologic disease, with many factors influencing its development and manifestations. Addiction is characterized by compulsive drug use, continued use despite harm, and craving. The term pseudoaddiction describes patient behaviors that may occur when pain is undertreated. Patients with unrelieved pain may become focused on obtaining medications and otherwise seem to engage in inappropriate drug-seeking behaviors. Behaviors such as illicit drug use and deception can occur in the patient’s efforts to obtain relief (Box 3.4). Pseudoaddiction can be distinguished from true addiction in that it resolves when pain is effectively treated.

**BOX 3.4**

**Addiction Behaviors**

**BEHAVIORS TYPICALLY SPECIFIC TO ADDICTION**
- Injecting oral formulations
- Concurrent abuse of alcohol or illicit drugs
- Selling or diversion of prescription drugs
- Prescription forgeries
- Obtaining drugs from nonmedicinal sources
- Repeated dose escalation
- Repeated visits to other EDs without informing prescriber
- Drug-related deterioration in function at work or socially
- Repeated resistance to changes in therapy, despite evidence of adverse drug effects

**BEHAVIORS LESS SPECIFIC TO ADDICTION**
- Aggressive complaining about the need for more drug
- Drug hoarding during periods of reduced symptoms
- Requesting specific drugs
- Openly acquiring drugs from other medicinal sources
- Occasional dose escalation or noncompliance
- Unapproved use of a drug to treat another symptom
- Resistance to change in therapy associated with tolerable side effects, with expression of anxiety related to the return of severe symptoms

ED, Emergency department.
Drug-Seeking Behavior. Some patients feign or exaggerate pain to receive opioids to abuse medications or sell them to others, defined as diversion. Opioid abuse and diversion is a growing problem, and the rapid growth in the number of opioid prescriptions has played a large role in rising rates of abuse and diversion. In recognition of diversion and abuse, many states have developed prescription monitoring programs that allow for an exchange of information among providers to detect frequent opioid prescriptions. Prescription-monitoring programs are effective in reducing the number of opioid prescriptions given to patients at risk for abuse or diversion as long as providers consider these data as a routine and integrated practice for patient care. Some states require consultation with the registry before prescribing opioids, but EDs may be exempted from this requirement because of patient flow issues.

A physician’s impression of behaviors believed to be associated with patient drug-seeking is associated with a reduction in the treatment of the patient’s pain (see Box 3.3). Unfortunately, prescriber perceptions are often complicated by differences between the health care provider and patient in regard to factors such as socioeconomic class, ethnic and racial background, and age, making them frequent sources of bias in the treatment of pain. Care must be taken to recognize these factors and consider their impact on treatment decisions. A thorough evaluation of drug-seeking behavior for a patient includes a review of medical records, prescription registries, and contact with other providers (eg, hospitals, primary care physicians), as available and appropriate. Unless confirmation can be derived through such an evaluation, a patient with apparent acute pain, as from a new injury, should be given the benefit of the doubt and treated as though her or his pain is legitimate. Patients with chronic conditions that can cause acute pain, such as dental caries, some gastrointestinal (GI) syndromes, or long-standing back pain, should be offered alternative pain management approaches, such as nerve block, nonopioid analgesia, or symptomatic treatment with antispasmodic agents until they can resume care with their usual health care providers.

Primary providers, chronic pain specialists, and others should note patient contracts, prescription details, and patterns of possible nontherapeutic drug-seeking behavior in the medical record, using objective terms and descriptions. Patients with repetitive episodes of drug-seeking events may benefit from a multidisciplinary review to establish specific recommendations for their care when they present to anyone other than their primary pain provider. Patients who are noncompliant with their treatment contract, and those who are known to be abusing or diverting opioid medications, should not be prescribed opioid medications from the ED.

Administration of Pain Control. The goal of opioid administration is to attain effective analgesia, with minimal adverse effects. The effects of opioids vary widely among individuals. There is no ceiling effect to their potency. There is also no standard, fixed, or weight-related dose that will consistently produce a given clinical effect. The correct dose that a particular patient requires at a particular time can only be determined by repeated assessment of the degree of pain relief and adverse effects. The use of opioids, therefore, requires titration based on frequent and accurate assessments (Fig. 3.7). The most effective and safe way to achieve pain relief is to use a deliberate IV titration.

The intramuscular (IM) route of administration of opioids has several disadvantages and is not advised for the treatment of acute pain (Box 3.5). The principal limitation of the IM route is its inability to titrate specific doses to desired treatment effects effectively. The time to achieve significant pain relief from an IM injection varies substantially for each patient and offers no therapeutic advantage over an oral medication dosing strategy.

Most patients with mild to moderate pain are best treated with oral (PO) opioids. If pain is severe, or if the patient is expected to require multiple doses of an agent for management, an IV route of administration is desirable. If an IV line cannot be established, and the patient cannot tolerate PO medications, the subcutaneous (SC) route is preferable to the IM route. SC injection is less painful than IM injection, with a similar onset of pain relief.

Opioids can be delivered through an oral transmucosal or intranasal mucosal route. Buprenorphine can be given via a sublingual route; whereas fentanyl is available in an impregnated sweetened matrix called Fentanyl Oralet (PO transmucosal fentanyl citrate). Nasal fentanyl, butorphanol, and sufentanil also produce rapid clinical effects via nasal mucosal absorption.

The optimal use of IV opioids requires the administration of an initial loading dose followed by assessment of the analgesic effect. Frequent (every 5–15 minutes) repeated doses should be administered until analgesia is achieved, followed by doses at regular intervals to prevent the return of significant discomfort (see Fig. 3.7).

Specific Agents

Morphine. IV morphine is often the first choice for treatment of acute severe pain in ED patients. Morphine is the opioid analgesic agent with which all other opioids are compared. When administered via the IV route, morphine reaches a peak of action in 15 to 20 minutes, with a half-life of 1.5 to 2 hours in healthy young adults and slightly longer in older adults. Its duration of action is 3 to 4 hours. An appropriate loading dose of morphine for acute severe pain is 0.1 to 0.15 mg/kg IV of ideal body weight, augmented by repeated doses of approximately half the initial dose every 5 to 15 minutes, depending on the severity of the pain and patient response.

Morphine is effective by oral administration; however, only 20% of the ingested morphine dose will reach tissues after first-pass metabolism, requiring a dose adjustment approximately five times that of an equipotent IV dose. The formerly held belief that morphine causes more smooth muscle spasm than other opioids, rendering it inappropriate for the treatment of patients with biliary or renal colic, has been thoroughly discredited.

Morphine is primarily metabolized by conjugation into a three- and six-conjugate forms in the liver. The three-conjugate form (normorphine) has no opioid analgesic activity and has rarely been associated with CNS side effects (eg, tremors, myoclonus, delirium, seizures). This risk is greatest in older patients and those with renal insufficiency, although it is generally not an issue in the ED. The six-conjugate form morphine metabolite is a strong mu and delta receptor agonist. This form plays an important role in the efficacy and duration of clinical effects.

Meperidine. Meperidine (Demerol), although once widely used, has several disadvantages compared with morphine and other parenteral opioids. Meperidine has no indication for use in the ED, and many hospitals have removed it from their

<table>

Pruritus, nausea, and vomiting may occur less frequently with hydromorphone administration than with morphine at equianalgesic doses. Hydromorphone is primarily conjugated in the liver to hydromorphone-3-glucuronide (H3G), an inactive metabolite, and is excreted through the renal system. As a result, hydromorphone is better tolerated than morphine, particularly in older patients and those with hepatic impairment. Patients with renal insufficiency may be at some risk of neurotoxicity after prolonged exposure due to H3G accumulation. Patients allergic to morphine do not consistently have cross-reactivity with hydromorphone. Hydromorphone can be given via the IV, SC, PR (per rectum), or PO route.

**Fentanyl.** Fentanyl is a synthetic opioid that is highly lipophilic; it produces analgesia within 1 to 2 minutes following IV infusion. Fentanyl redistributes rapidly, and its duration of therapeutic action is approximately 30 to 60 minutes. Fentanyl is metabolized by the P450 system into inactive metabolites. Drug accumulation and toxicity may occur after tissue saturation following a prolonged infusion, but this is unlikely to occur during acute therapy. The short duration of action for fentanyl makes it highly titratable and ideal for use in patients who require serial examinations, such as trauma patients with possible occult head injury.
Fentanyl causes less histamine release than morphine and is associated with fewer peripheral effects at an equianalgesic dose. Fentanyl is an excellent choice for treating pain in patients with bronchospastic lung disease or a history of opioid-associated pruritus. Fentanyl is more frequently associated with respiratory depression than morphine. Patients receiving fentanyl infusions should be monitored with direct observation, supplemented by pulse oximetry.

The ED use of fentanyl is associated with a very low incidence (1.1%) of serious complications. High or repeated fentanyl doses may produce muscle rigidity. This side effect, so-called rigid chest syndrome, usually occurs with anesthetic doses greater than 15 mcg/kg, but also has been reported during use for procedural sedation; it may be so severe that it interferes with respiration. Rigid chest attributed to fentanyl is exceedingly rare at doses typically used for acute analgesia. Chest rigidity, when observed to occur, generally responds to naloxone, but neuromuscular blockade may be necessary if naloxone reversal is not successful.

Fentanyl can be administered IV, transmucosally, or transdermally. Nebulized or intranasal fentanyl has been described for the treatment of acute pain in patients without IV access at doses of 3 mcg/kg.

**Oxycodone.** Oxycodone is a strong opioid agonist that is highly bioavailable in an oral form. Oxycodone is widely sold in combination with acetaminophen or aspirin as well as by itself and is also available in long-acting PO formulations. Oxycodone for acute pain should be prescribed in the noncombination form—that is, as pure oxycodone—to allow a balance between oxycodone and a nonopioid medication. Baseline administration of a nonopioid medication, supplemented by titrated doses of oxycodone, will achieve the optimal effect, with the fewest side effects. Oxycodone bioavailability is much higher than other opioids. It is quickly and efficiently absorbed, which may be a causative factor in its high abuse potential.

Oxycodone is not available in a parenteral form in the United States, although studies have demonstrated its IV form to be equianalgesic to morphine. Similar to other opioids, the analgesic effects of oxycodone are dose-dependent. A 15-mg oxycodone dose has similar efficacy to 10 mg of IV morphine. The onset of action of PO oxycodone is approximately 20 to 30 minutes.

Oxycodone undergoes hepatic metabolism into oxymorphone, a strong opioid agonist that principally accounts for its analgesic effects. Similar to codeine, approximately 10% of patients do not metabolize oxycodone well and are unable to generate the functional metabolite, oxymorphone. This defect in metabolism renders these patients unable to achieve clinically meaningful pain relief with typical dosing strategies and may require very large doses to achieve analgesia. This effect can also be caused by agents that compete with oxycodone for CYP2D6 metabolism, such as neuroleptics, tricyclic antidepressants, and selective serotonin reuptake inhibitors. Cases of serotonin syndrome have been reported when serotonin reuptake inhibitors and oxycodone are given together, likely due to this metabolic interaction.

**Hydrocodone.** Hydrocodone is metabolized in the liver to hydromorphone and is typically given orally. Hydrocodone provides greater pain relief when combined with acetaminophen or NSAIDs than either component alone. Hydrocodone combinations are less effective than oxycodone-acetaminophen combinations. Hydrocodone clinical analgesia effects typically last 4 hours, with typical dosing of 5 to 20 mg. As with oxycodone, hydrocodone should be prescribed in pure form, not in a combination agent, to allow individual titration of opioid and nonopioid analgesics.

**Codeine.** Codeine is a weak opioid receptor agonist, usually prescribed in combination with acetaminophen, but has little, if any, role in the modern ambulatory treatment of pain. Codeine is thought to exert its effects through metabolism into morphine and other active hepatic metabolites.

Approximately 10% of the population metabolizes codeine poorly. The effect of this genetic trait is a reduction in active analgesic metabolites and an enhancement in deleterious side effects, including nausea, constipation, and pruritus. Although often historically prescribed for mild to moderate pain, codeine is a poor choice for analgesia due to its tendency to cause side effects, particularly nausea, cramping, and constipation, at doses that provide minimal analgesia. Despite its weak opioid agonist characteristics, codeine has been widely abused.

**Methadone.** Methadone has several unique features that distinguish it from other opioids. It has no known neurotoxic or active metabolites and has high bioavailability. In addition to being a strong opioid agonist, methadone also has N-methyl-D-aspartate antagonist and serotonin reuptake qualities. It has a slow elimination half-life of 27 hours due to its lipophilicity and tissue distribution. This slow clearance of methadone is the basis for its use in maintenance therapy, given that it can delay the onset of opioid withdrawal symptoms for up to 24 hours. The duration of its analgesic effects is closer to 6 to 8 hours. The discrepancy between the duration of action of analgesia and duration of the prevention of withdrawal symptoms is due to the biphasic elimination of the drug and its redistribution.

**Naloxone.** Naloxone is an opioid antagonist that reverses the effects of opioids and is used in the setting of adverse, opioid-induced events, such as opioid overdose. It can precipitate physiologic withdrawal in patients who are opioid-dependent. The duration of action of naloxone is approximately 45 minutes, which is shorter than that of most opioids, and care must be taken to monitor for the recurrence of opioid adverse events following this time period. Naloxone can be given IV, IM, SC, or via an endotracheal tube, but is typically given in titrated doses of 0.2 mg IV until reversal of any adverse opioid effect is observed. In the setting of adverse events from opioid treatment, usually respiratory depression, careful titration allows for the smallest dose possible to be administered so that its analgesic effect of the opioid. Naloxone, 0.4-mg autoinjectors, are available for outpatient use to prevent overdose complications. Early results of distributing these autoinjectors to opioid-dependent patients have shown that they are effective in preventing overdose complications.

**Tramadol.** Tramadol is a synthetic oral analgesic that is a weak mu agonist, with some serotonin and norepinephrine reuptake qualities. Its analgesic properties are thought to be primarily due to its receptor agonist activity. Tramadol-induced analgesia is partially reversed by naloxone, suggesting that other properties play a role in its therapeutic effects. Tramadol, as a selective mu agonist without kappa agonist effects, should not cause physiologic dependence, although tramadol use is associated with abuse. Tramadol should be used with caution in patients addicted to opioids.

Tramadol is metabolized in the liver by the cytochrome P450 system. One of its metabolites, M1, has a greater mu receptor affinity than tramadol and has an elimination half-life of 9 hours. Tramadol appears to have effects on GABA, norepinephrine, and serotonin receptors and the reuptake of the neurotransmitters. These properties may serve to activate descending pain modulation pathways.

Compared with traditional opioids, low-dose tramadol has a more favorable side effect profile and may present a lower risk of addiction with chronic use. The most common tramadol side effects are nausea, vomiting, dizziness, orthostatic hypotension, and sedation. These side effects are seen in as many as 17% of patients using the drug for chronic pain, with slightly lower rates in patients receiving controlled-release versions. Tramadol lowers the seizure threshold and therefore provokes isolated seizures in
selected patients. The use of tramadol with other serotonergic medications (eg, selective serotonin receptor inhibitors, monoamine oxidase inhibitors, serotonin norepinephrine reuptake inhibitors) is associated with serotonin syndrome.

Tramadol is effective at low doses. At increasing doses, it is associated with nausea and vomiting, limiting its use to low doses and effectively creating a therapeutic ceiling to its clinical use. Tramadol, 37.5 mg, combined with acetaminophen, 325 mg, appears to have similar efficacy to hydrocodone, 5 mg, combined with acetaminophen, 325 mg. As with hydrocodone and oxycodone, tramadol should be prescribed in pure form, allowing accurate dosage adjustment from other agents.

**Tapentadol.** Tapentadol is a mu opioid agonist and norepinephrine reuptake inhibitor. It is thought to control acute pain via both these pathways. Tapentadol has similar efficacy to oxycodone for the treatment of acute pain, with less frequent nausea and vomiting. Its dual mechanism of action makes it a potentially effective drug for use in chronic pain, although it has not been studied for this.

**Opioid Agonist-Antagonist Analgesic Agents.** The agonist-antagonist group of opioids was synthesized in an attempt to provide analgesia with little or no respiratory depression or abuse potential. It is believed that the analgesia provided by these agents is caused by agonist action at the kappa receptors, whereas the ceiling for respiratory depression is created by mu receptor antagonism. Agonist-antagonist agents have rates of abuse similar to those for standard opioids and a ceiling effect to their analgesia that limits their use. Clinical application of these drugs is typically in situations in which brief, limited analgesia is needed and respiratory depression is the principal adverse concern, such as in the perinatal period.

Nalbuphine is a commonly used agonist-antagonist. The half-life of nalbuphine is 3.5 hours, and the effects of renal or hepatic disease on metabolism are not completely known. The usual therapeutic parenteral dose is 10 mg, which has an analgesic efficacy similar to morphine, 10 mg. As with all other opioids, the dose must be individualized for the specific patient and clinical needs.

**Opioid Use for Acute Abdominal Pain.** Historically, pain treatment was withheld from patients with abdominal pain to avoid confounding a diagnosis. These recommendations date from the turn of the 20th century, predating modern diagnostic techniques, and have no place in modern emergency care. Multiple studies have confirmed the safety of providing effective opioid analgesia to patients with undiagnosed abdominal pain.

**Nonopioid Analgesic Agents**

**Acetaminophen.** Acetaminophen is the first-line agent for the treatment of acute and chronic pain and is the safest pharmacologic option for pain in children and adults. It has a high toxic-to-therapeutic ratio and lacks significant drug interactions compared with other pain medications.

Although acetaminophen has been in use since the 1880s, its pharmacologic mechanism of action is unknown. Acetaminophen has known analgesic and antipyretic activity, with no known peripheral antiinflammatory effects. Its activity may be due to the inhibition of prostaglandin endoperoxide H₂ synthase and a cyclooxygenase isoenzyme centrally. It may also affect the activation of beta-endorphin centrally. The analgesic actions of acetaminophen are comparable in magnitude to those of NSAIDs. The analgesic effects of the combination of acetaminophen with an NSAID are additive.

Acetaminophen is metabolized in the liver primarily through conjugation to a sulfate or glucuronide. A minor pathway for the oxidative metabolism of acetaminophen produces the toxic metabolite N-acetyl-p-benzoquinone imine (NAPQI). NAPQI requires glutathione for detoxification and elimination. Hepatic toxicity can occur when glutathione pathways are overwhelmed by an increase in NAPQI or a decrease in glutathione levels. Hepatic toxicity is rare with ingestions less than 10 g in a 24-hour period, unless underlying liver disease exists or there is concomitant ethanol abuse. In the latter cases, therapeutic doses can cause clinical hepatotoxicity.

Acetaminophen is generally well tolerated when used at therapeutic doses. Mild rashes are rarely reported, as is bone marrow suppression, manifested by neutropenia, thrombocytopenia, and agranulocytosis. Its use is associated with several important drug interactions. Many anticonvulsants, including phenytoin, barbiturates, and carbamazepine, induce hepatic microsomal enzymes. Increased conversion of acetaminophen to its toxic metabolite may occur in patients who are taking anticonvulsants, but this is rarely of clinical significance in the context of the usual doses for pain management.

Although uncommon, drug interactions resulting in an increased international normalized ratio (INR) have been reported for patients taking acetaminophen and warfarin, particularly among patients taking high doses of acetaminophen (>9100 mg/week). Chronic use of acetaminophen should be avoided in patients with hepatic or renal disease. Renal failure can worsen with acetaminophen use, but the mechanism is unknown. Patients with a history of salicylate hypersensitivity characterized by urticaria have an 11% cross-reactivity to acetaminophen, and the agent should be used with caution in this group.

For mild analgesia and fever reduction, acetaminophen is the first-line agent and is a first choice for use in combination with other agents, usually opioids, in the treatment of patients with more severe pain. The recommended dose of acetaminophen for an adult is 650 to 1000 mg every 4 to 6 hours, not to exceed 4000 mg/day.

**Nonsteroidal Antiinflammatory Drugs**

NSAIDs inhibit cyclooxygenase (COX) and, as a result, the synthesis of prostaglandin, a key mediator of inflammation. The analgesic effect of NSAIDs is peripherally mediated by decreasing prostaglandin levels and effectively raising the threshold of activation of nociceptors. NSAIDs have synergistic effects with opioids and can reduce the amount of opioids needed to achieve pain relief.

Two COX isoenzymes mediate prostaglandin synthesis. COX-1 is present in all cells and plays an important role in homeostatic functions. COX-2 is induced by injury or inflammation and generates prostaglandins as part of the inflammatory process. Nonselective NSAIDs inhibit both COX-1 and COX-2, which results in multiple beneficial effects (eg, reduction of inflammation, pain, fever) but also some important undesirable effects.

As a group, and because of their common use, NSAIDs are responsible for more serious drug-related side effects than any other class of analgesic drugs. The major side effects of NSAID analgesic agents are GI bleeding, renal failure, anaphylaxis, and platelet dysfunction. Most of these side effects occur in patients who are taking NSAIDs for chronic conditions. It is estimated that more than 100,000 hospital admissions and approximately 16,500 deaths each year from GI bleeding are related to NSAID use for osteoarthritis and rheumatoid arthritis. One survey has estimated that for every 100,000 people taking NSAIDs, there are 300 GI-related deaths, 5 hepatic-related deaths, 4 renal-related deaths, and some congestive heart failure–related deaths.

Bone and cartilage healing and repair during NSAID use is a concern in patients with acute fractures. There is limited evidence to suggest that prostaglandins promote bone formation and that

**Acetaminophen.** Acetaminophen is metabolized in the liver primarily through conjugation to a sulfate or glucuronide. A minor pathway for the oxidative metabolism of acetaminophen produces the toxic metabolite N-acetyl-p-benzoquinone imine (NAPQI). NAPQI requires glutathione for detoxification and elimination. Hepatic toxicity can occur when glutathione pathways are overwhelmed by an increase in NAPQI or a decrease in glutathione levels. Hepatic toxicity is rare with ingestions less than 10 g in a 24-hour period, unless underlying liver disease exists or there is concomitant ethanol abuse. In the latter cases, therapeutic doses can cause clinical hepatotoxicity.

Acetaminophen is generally well tolerated when used at therapeutic doses. Mild rashes are rarely reported, as is bone marrow suppression, manifested by neutropenia, thrombocytopenia, and agranulocytosis. Its use is associated with several important drug interactions. Many anticonvulsants, including phenytoin, barbiturates, and carbamazepine, induce hepatic microsomal enzymes. Increased conversion of acetaminophen to its toxic metabolite may occur in patients who are taking anticonvulsants, but this is rarely of clinical significance in the context of the usual doses for pain management.

Although uncommon, drug interactions resulting in an increased international normalized ratio (INR) have been reported for patients taking acetaminophen and warfarin, particularly among patients taking high doses of acetaminophen (>9100 mg/week). Chronic use of acetaminophen should be avoided in patients with hepatic or renal disease. Renal failure can worsen with acetaminophen use, but the mechanism is unknown. Patients with a history of salicylate hypersensitivity characterized by urticaria have an 11% cross-reactivity to acetaminophen, and the agent should be used with caution in this group.

For mild analgesia and fever reduction, acetaminophen is the first-line agent and is a first choice for use in combination with other agents, usually opioids, in the treatment of patients with more severe pain. The recommended dose of acetaminophen for an adult is 650 to 1000 mg every 4 to 6 hours, not to exceed 4000 mg/day.

**Nonsteroidal Antiinflammatory Drugs**

NSAIDs inhibit cyclooxygenase (COX) and, as a result, the synthesis of prostaglandin, a key mediator of inflammation. The analgesic effect of NSAIDs is peripherally mediated by decreasing prostaglandin levels and effectively raising the threshold of activation of nociceptors. NSAIDs have synergistic effects with opioids and can reduce the amount of opioids needed to achieve pain relief.

Two COX isoenzymes mediate prostaglandin synthesis. COX-1 is present in all cells and plays an important role in homeostatic functions. COX-2 is induced by injury or inflammation and generates prostaglandins as part of the inflammatory process. Nonselective NSAIDs inhibit both COX-1 and COX-2, which results in multiple beneficial effects (eg, reduction of inflammation, pain, fever) but also some important undesirable effects.

As a group, and because of their common use, NSAIDs are responsible for more serious drug-related side effects than any other class of analgesic drugs. The major side effects of NSAID analgesic agents are GI bleeding, renal failure, anaphylaxis, and platelet dysfunction. Most of these side effects occur in patients who are taking NSAIDs for chronic conditions. It is estimated that more than 100,000 hospital admissions and approximately 16,500 deaths each year from GI bleeding are related to NSAID use for osteoarthritis and rheumatoid arthritis. One survey has estimated that for every 100,000 people taking NSAIDs, there are 300 GI-related deaths, 5 hepatic-related deaths, 4 renal-related deaths, and some congestive heart failure–related deaths.

Bone and cartilage healing and repair during NSAID use is a concern in patients with acute fractures. There is limited evidence to suggest that prostaglandins promote bone formation and that
NSAIDs might inhibit the process. This issue has not been thoroughly pursued or established through properly conducted studies. There is no human subject evidence that short-term use of NSAIDs for analgesia after fracture is deleterious to healing.

COX also promotes the production of prostacyclin, a vasodilator that increases GI mucosal perfusion. In the stomach, COX-1 increases bicarbonate and mucus production, important for protecting the mucosal lining. Inhibition of COX-1 compromises these protective functions, predisposing patients to ulcers and bleeding, which are then exacerbated by concomitant NSAID-induced platelet dysfunction.

COX-1 and COX-2 affect the cardiovascular system through the production of endothelial prostacyclin (vasodilatory) and thromboxane (platelet aggregation). Inhibition of COX-1 causes antiplatelet activity that may be cardioprotective by inhibiting thromboxane production more than prostacyclin. Inhibition of COX-2 inhibits prostacyclin production more than thromboxane and may produce prothrombotic effects, increasing the risk of cardiovascular events. In the case of nonselective COX inhibitors, these two effects appear to balance each other out, resulting in few changes in cardiovascular risk in studies of these drugs. In the case of selective COX-2 inhibitors, this may result in an increase in cardiovascular risk and has limited the use of these agents.

Prostaglandin produced by COX-1 causes renal vasodilation that maintains renal blood flow and the glomerular filtration rate (GFR). Inhibition of COX-1, especially in volume-depleted patients, can result in a decreased GFR and acute renal insufficiency. Sodium and water retention, hypertension, hyperkalemia, and acute renal failure may also ensue, particularly in patients with congestive heart failure.

The most common adverse effect of NSAIDs is GI mucosal injury. In patients taking NSAIDs continuously for 1 year, it has been found that 10% to 60% will develop abdominal pain, dyspepsia, or nausea and 2% to 4% will develop symptomatic ulcers. Risk factors include age, concomitant use of warfarin or corticosteroids, congestive heart failure, diabetes, and coronary artery disease. There is evidence that cytoprotective agents such as misoprostol and proton pump inhibitors reduce this risk. The relative risk for GI side effects varies with various NSAIDs and treatment strategies (Table 3.5).

Drug Interactions With Nonsteroidal Antiinflammatory Drugs

Aspirin. NSAIDs may impair the cardioprotective effect of aspirin, although the available evidence is unclear and the use of daily aspirin for cardiac prophylaxis should not deter the prescribing of an NSAID for acute pain or inflammation.

Oral Anticoagulants. The antiplatelet effects of NSAIDs add to the anticoagulant properties of warfarin, compounding the risk of significant bleeding complications, especially from GI ulcers. Furthermore, NSAIDs displace protein-bound warfarin and cause subsequent increases in prothrombin times at a constant warfarin dose. NSAID use is generally avoided in patients who are taking warfarin.

Angiotensin-Converting Enzyme Inhibitors. Concurrent use of NSAIDs with angiotensin-converting enzyme (ACE) inhibitors may impair renal function and increase the antihypertensive effects of ACE inhibitors.

Diuretics. Patients who are taking diuretics have a greater risk of developing renal failure due to NSAID-mediated decreased renal blood flow. Also, the natriuretic response to diuretics depends in part on prostaglandin-mediated vasodilation.

Glucocorticoids. Patients on corticosteroids have an increased risk of peptic ulcer disease. NSAIDs should generally be avoided in patients concurrently taking glucocorticoids unless closely supervised by a physician.

### Lithium

NSAIDs enhance lithium reabsorption and may directly reduce lithium excretion, leading to increased lithium levels. CNS symptoms (eg, drowsiness, confusion, vertigo, convulsions, tremors), cardiac dysrhythmias, and QRS widening are warnings of lithium toxicity. The lithium dosage should be reduced when an NSAID is prescribed.

Nonselective Cyclooxygenase Inhibitor Selection. NSAIDs combine analgesia and antiinflammatory effects with low abuse potential and many different side effects compared to opioid agents. Oral NSAIDs can be as effective as oral opioids for mild to moderate pain. Parenteral NSAIDs offer little advantage over their PO forms. Different patients respond differently to the beneficial effects and side effects of different NSAIDs. Therefore, some individual experimentation may be necessary to determine the best NSAID choice for a particular patient. No particular NSAID has been proven to be superior for any indication. Drug selection should depend on availability, side effect profile, convenience, and cost. Patients at risk for adverse events using NSAIDs are listed in Box 3.6.

**Ketorolac Tromethamine.** Ketorolac was the first nonopioid analgesic agent available for parenteral use in the United States. For acute pain management, ketorolac is rarely indicated in the patient able to receive oral medications, given that 60 mg of ketorolac administered IM is not clinically superior to 800 mg of oral ibuprofen. Additionally, NSAID agents can be administered at a fraction of the cost of parenteral routes. The main indication for ketorolac use is in the early treatment of renal colic (accompanied by a loading dose of IV morphine) because of the difficulty in colic patients receiving and tolerating of oral medications.

**Ibuprofen.** Ibuprofen is the most widely used agent in the NSAID class. It is available over the counter in a variety of preparations, including tablet, liquid suspension, and suppository forms. Ibuprofen is rapidly absorbed from the upper GI tract and has minimal interaction with other medications. The adult analgesic dose is 400 mg. No NSAID is more effective as an analgesic than ibuprofen, 400 mg, including ibuprofen, 600 and 800 mg.

GI, Gastrointestinal.
BOX 3.6

Patients at Risk for Adverse Events During Nonsteroidal Antiinflammatory Drug (NSAID) Therapy

1. Patients with dehydration, hypovolemia or who have impaired renal function are at increased risk for decreasing renal function or renal failure.
2. Patients with liver disease or congestive heart failure—in particular, those already taking ACE inhibitors, ARBs, or diuretics—in whom liver or heart conditions may worsen.
3. Older patients are at increased risk for GI and renal events.
4. Patients with asthma and known aspirin hypersensitivity are increased risk of bronchospasm.
5. Women in the third trimester of pregnancy—NSAIDs may prolong gestation or prematurely close the ductus arteriosus.
6. Patients who use tobacco or ethanol with a history of gastritis or peptic ulcer disease are at increased risk for peptic ulcer or GI bleed.

ACE, Angiotensin-converting enzyme; ARB, angiotensin II receptor blocker; GI, gastrointestinal.

Skeletal Muscle Relaxants. Skeletal muscle relaxants have been advocated as an adjunct to analgesics in the management of musculoskeletal pain with a spasm component, principally back pain. Despite the common use of skeletal muscle relaxants, little data exist supporting their role in the treatment of pain. Studies have demonstrated that muscle relaxants, such as cyclobenzaprine, are indistinguishable from ibuprofen in analgesic effect but have an increased side effect profile.

Skeletal muscle relaxants should not be used in the treatment of acute musculoskeletal pain as a substitute for proper doses of effective analgesics unless there is a high degree of anxiety accompanying the pain. Benzodiazepines are not recommended for the routine treatment of musculoskeletal pain. In patients exhibiting a great deal of muscle spasm with anxiety, a benzodiazepine such as diazepam, 5 mg tid, or lorazepam, 1 mg bid, may be an effective therapeutic adjunct. Benzodiazepines have hypnotic, anxiolytic, antiepileptic, and antispasmodic properties. Muscle relaxation with these agents is probably due to GABA-mediated presynaptic inhibition at the spinal cord level.

Nitrous Oxide–Oxygen Mixtures. The analgesic and anesthetic properties of nitrous oxide were discovered more than 200 years ago and is one of the original forms of patient-controlled analgesia. Nitrous oxide–oxygen mixtures can be used in the ED or the out-of-hospital care setting to reduce anxiety in patients and manage mild to moderate pain states. Combined with oxygen, a mixture of nitrous oxide and oxygen in a 50:50 ratio is safe when self-administered by the patient.

Nitrous oxide and oxygen administered by nasal mask have long been used by dentists for the treatment of pain and anxiety. Experience in emergency medicine with nitrous oxide–oxygen mixtures is greatest in the ratio of a 50:50 mixture with a self-administered, hand-held mask.

The mechanism of analgesia and anxiolysis with nitrous oxide have not been fully delineated. The nature of its analgesic effect appears to be similar to that of low-dose opioids, although some of the anxiolytic effects of nitrous oxide appear to have more in common with benzodiazepines than opioids. It has been postulated that nitrous exerts an effect on GABA receptors.

Nitrous preparations are often administered in a two-tank system, with a fixed-ratio nitrous oxide–oxygen mixture delivered to the patient through a demand valve activated with inhalation through a facemask or mouthpiece. A negative pressure of 3 to 5 cm H2O must be produced within the mask or mouthpiece to activate the flow of gas, limiting the use of these devices in very small children. Having the patient hold the mask to the face allows him or her to titrate the dose to an effective level. In 10% to 15% of patients, nitrous oxide is ineffective. It is much more potent as an anxiolytic than as an analgesic agent and can be supplemented with other analgesics.

Nitrous oxide is a folate antagonist and is strictly contraindicated in pregnant patients. Advanced scavenger systems are necessary to allow the safe use of nitrous oxide in the ED to avoid accumulation and toxicity in health care workers, especially if pregnant. Nitrous oxide–oxygen mixtures are relatively or absolutely contraindicated in patients with a decreased level of consciousness who are unable to follow instructions. Patients with severe chronic obstructive pulmonary disease who retain CO2 should be given nitrous oxide–oxygen mixtures carefully, given that the mixture contains 50% oxygen, which may predispose to hypercapnia. Because nitrous oxide diffuses into body cavities, it can worsen a pneumothorax or bowel obstruction.

Minor side effects of nitrous analgesic gas mixtures have been reported in 5% to 50% of patients. The most common adverse effect is lightheadedness, with paresthesias and nausea reported less frequently. No documented adverse hemodynamic effects have occurred with the self-administered forms of this agent. Side effects attributed to nitrous oxide usually resolve within minutes of discontinuation.

Ketamine. Ketamine is a drug that has typically been used primarily as a dissociative anesthetic for procedural sedation; it is one of the most effective and widely used drugs for procedural anesthesia worldwide. Ketamine has also been evaluated for low-dose use as an analgesic.38-41 Low-dose ketamine has been shown to be similar to morphine in its analgesic effect when used alone and as an additive to opioids when used in conjunction with them at doses of 0.1 to 0.3 mg/kg IV (one-tenth to one-third of a typical dose used for dissociative sedation).

The principle side effects of ketamine are dysphoria, vomiting, and hypersalivation. Ketamine appears to be effective via the N-methyl-D-aspartate receptor, a different pathway from opioids, acetaminophen, or NSAIDs, giving it potential to affect analgesia when other agents are limited by their adverse effects. It is likely that the use of low-dose ketamine as an analgesic will likely increase as its role and safety are further explored.

Local Anesthesia

Mechanism of Action. Peripheral nerves are responsible for transmitting pain information from pain receptors to the spinal cord. Each fiber consists of an axon surrounded by a covering called the Schwann cell. A myelinated axon is one covered by the projection of a Schwann cell that wraps itself many times around the axon; hence, the term myelin sheath.

Local anesthetics are much more effective at penetrating unmyelinated or lightly myelinated fibers than heavily myelinated ones. This difference explains the finding that local anesthetic agents provide sensory block without motor neuron effects (see Table 3.1).

Local anesthetic agents reversibly block lipid membrane sodium channels and prevent the influx of sodium ions into the axon, blocking depolarization and the nerve action potential. After injection of a local anesthetic, tissue buffers increase the pH of the solution surrounding the agent, driving much of the water-soluble acidic form to its lipid-soluble nonionic form. The lipid-soluble phase of the drug is able to penetrate the axon lipid membrane, where it then ionizes and enters the sodium channel, blocking the ability of sodium to enter the cell.
**Classes of Local Anesthetic Agents.** Local anesthetic agents are chemical compounds that consist of an aromatic and amine group separated by an ester (eg, procaine, chloroprocaine, tetracaine) or an amide (eg, lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine) intermediate chain. Esters are unstable in solution and are metabolized in the body by the plasma enzyme cholinesterase. The amides, after absorption into the body, are destroyed by enzymes in the liver. The main considerations in the clinical use of these agents are potency, duration of anesthesia, and speed of onset (Table 3.6). The lipid solubility of an agent determines its potency. Less potent local anesthetics must be given in more concentrated forms and in larger doses to achieve an equivalent effect.

The duration of anesthetic agent action is determined by its protein-binding affinity to protein in the sodium channel. The speed of onset of any local anesthetic agent is directly related to its diffusion through tissues to the nerve, as determined by its pKa (dissociation constant)—the pH at which 50% is ionized. After injection, the anesthetic agent is in two forms, ionized and nonionized. Only the nonionized form of the drug diffuses into nerves. Therefore, solutions with a low pKₐ have a more rapid onset of anesthesia.

Low tissue pH (5 or 6) in surrounding infected tissue delays the onset of local anesthesia in cases such as abscess incision and drainage by keeping more of the agent in an ionized state. The onset of local anesthesia in cases such as abscess incision and drainage by keeping more of the agent in an ionized state. The onset of anesthetic action can be hastened by the alkalinization of the solution carrying the drug, which also decreases its irritant effect (pain) on injection. This can be done clinically by adding sodium bicarbonate solution to the anesthetic at a ratio determined by the pKₐ of the agent. Anesthetic agents, except cocaine, are vasoconstrictors, which tend to shorten the duration of anesthesia. Injection of the solutions into vascular tissues not only shortens the duration of anesthesia but also increases systemic absorption and increase in tissue toxicity and should be avoided in areas with poor collateral circulation.

**Allergic Reactions.** True allergies to local anesthetics are rare. When an allergy to local anesthetics is reported, the offending substance is often one of the preservatives used. Because the amide agents and amino ester agents do not cross-react and use different preservatives, a patient may be given a medication from another class if the allergy history is consistent with a specific anesthetic group. In those patients who report they are allergic to all “-caine” anesthetic agents, and the allergy is believed to be legitimate, diphenhydramine can be used as an alternate agent. Diphenhydramine may be used with 1 mL of a 50-mg/mL ampule diluted with saline to 5 or 10 mL (1%–0.5% solution) for local infiltration or nerve block. Diphenhydramine may cause direct tissue toxicity and should be avoided in areas with poor collateral circulation.

**Local and Systemic Toxicity**

**Local Toxicity.** Local anesthetic agents, depending on the concentration, can be directly toxic to tissue. Also, it is possible that the use of a vasoconstrictor in an anesthetic solution may produce a reduction in blood flow that could increase wound healing time and vulnerability of the wound to infection. However, this concept has never been formally demonstrated.

**Systemic Toxicity.** Systemic toxicity of local anesthetics occurs when a sufficient quantity of the drug accumulates in the body so that sodium channel blockade occurs in the heart or brain. There is a dose-related clinical progression of local anesthetic toxicity, from subtle neurologic symptoms to seizures to cardiovascular collapse.

All local anesthetics produce systemic toxicity at a sufficiently high blood or CNS concentration. Each local anesthetic has a range of therapeutic safety beyond which systemic toxicity is more likely to occur (Table 3.7). Overdose of local anesthetics may occur more commonly in patients with large wounds and in patients with a low body mass index.

The more lipophilic anesthetic agents (eg, etidocaine, bupivacaine) are more cardiotoxic. Cardiac toxicity may also occur if epinephrine-containing anesthetics are inadvertently injected intravenously. Special care should be exercised in children and

All maximum doses should be reduced 20% to 25% in very young, old, and very sick patients.
A lidocaine level of 0.5 to 2.0 g/mL may be reached for every 100 mg of lidocaine infiltrated for blocks.
Epinephrine adds to the potential cardiac toxicity of this drug.
Not to be used for pudendal blocks or IV regional anesthesia; not recommended for children younger than 12 years.

Adapted from Stewart RD: Local anesthesia. In Paris PM, Stewart RD, editors: Pain management in emergency medicine, Norwalk, CT, 1988, Appleton & Lange.
when performing blocks known to produce high blood levels of the anesthetic agent (eg, intercostal). In pediatric patients, the maximum agent dose should be calculated before administration.

A wide variety of symptoms may be experienced from local anesthetic toxicity. These include lightheadedness, headache, tinnitus, paresthesias, muscle spasm, and confusion. In addition, benzocaine has been associated with methemoglobinemia. The degree to which CNS symptoms are experienced is directly related to the blood level of the local anesthetic.

CNS toxicity from anesthetic agents may result in seizures. A typical clinical progression usually begins with circumoral paresthesias, dysarthria, and a report of tinnitus or similar auditory phenomenon. These events may be followed by a decreased level of consciousness progressing to confusion, seizures, and coma. Longer acting, more potent agents (eg, bupivacaine, etidocaine) are more likely than lidocaine to cause CNS symptoms at lower blood levels. Local anesthetic-induced seizures should be treated with IV benzodiazepines and may be refractory to normal dosing of neuroleptic medications.

Local anesthetic agents also have direct effects on cardiac automaticity, conductivity, contractility, and vascular tone. Management of cardiovascular collapse caused by toxic levels of local anesthetic agents should follow standard advanced cardiac life support guidelines. Unless the overdose is massive, the toxicity should be relatively short-lived, given the redistribution of the lipophilic agents.

Reducing the Pain of Local Anesthetic Injection. Many techniques can be used to reduce the pain of anesthetic injection (Box 3.7). Distraction by manual methods such as scratching, jiggling, or repetitively pinching the skin during needle puncture or injection reduces the discomfort experienced during local anesthetic injection. Injecting the agent slowly is the principle method to reduce injection pain. Injection into the edges of a wound is less painful than injection through intact skin. Warming the anesthetic and the application of a topical anesthetic agent can also decrease the initial sensation associated with needle injection.

The addition of sodium bicarbonate to lidocaine prior to injection reduces anesthetic injection pain. A standard solution of sodium bicarbonate (8.4% in 50 mL) can be added to a syringe containing lidocaine in a ratio of 1:10 (eg, 1 mL bicarbonate to 10 mL lidocaine, or 0.5 mL to 5 mL). Buffered lidocaine can be stocked in the ED and is effective for up to 1 week.

Topical Anesthesia

Topical anesthetics are generally of two types, those that can be applied to intact skin and those used on open skin. Topical agents are particularly useful in pediatric patients intimidated by needles. These agents may help decrease the intensity of superficial stimuli. The long application time and limited analgesia are the principal drawbacks for these strategies. In some patients, however, the strategy of applying the topical anesthetic and delaying the procedure until there will be less pain can be an effective tool in controlling pain and the response to subsequent interventions.

Topical Anesthetics Applied to Intact Skin

Eutectic Mixture of Local Anesthetics. A eutectic mixture of local anesthetics (EMLA) is a mixture of lidocaine and prilocaine in an alkaline oil mixture in which the anesthetics are primarily in their nonionized form. This format allows diffusion through intact skin. The term eutectic refers to mixtures that result in a melting point higher than that of either agent alone.

For clinical use, an EMLA mixture should be applied to the desired area with an occlusive dressing 30 to 60 minutes before the procedure is performed. Heating EMLA for 20 minutes improves analgesia but is less effective than a routine 60-minute application, with or without heat. The duration of action after a 60-minute application is 1 to 5 hours.

Indications for the use of EMLA include venipuncture, arterial puncture, lumbar puncture, or arthrocentesis when a 30- to 60-minute delay in performing the procedure is not an impediment. EMLA can be applied in triage, particularly for pediatric patients, with an IV started later in the ED with little or no pain.

Ethyl Chloride and Fluoromethane Sprays. Ethyl chloride and fluoromethane sprays are occasionally used for superficial analgesia. The agents evaporate quickly and cool the skin, providing brief (<1-minute) local anesthesia due to the sensation. The induced analgesia is brief. Any injection or incision should be made immediately after the application of the agent.

Agents Applied to Mucosal Surfaces

Cocaine. Cocaine is unique among local anesthetic agents given that it is a potent vasoconstrictor in addition to being an anesthetic that can be applied to mucosal surfaces. Cocaine is frequently used in the nose, for which a 4% (40 mg/mL) solution provides rapid anesthesia for the treatment of epistaxis and other nasal procedures. Although the maximum safe dose is unknown, no more than 200 mg is typically applied in adults. Cocaine should not be used in patients with known coronary artery disease due to the potential for coronary artery vasoconstriction.

Lidocaine. Both 2% and 4% lidocaine solutions are available in a viscous matrix for use on mucosal surfaces. Gel lidocaine can be used in nasal procedures, including the passing of nasogastric tubes and gastric lavage tubes. It can also be used for urethral anesthesia during Foley catheter placement. To be effective, lidocaine gel preparations must be injected into the urethra with a catheter tip syringe and be in contact with the area for 5 to 20 minutes. Lidocaine spray (4% or 10%) is useful for upper airway anesthesia, including intranasal use for nasogastric tube insertion.

Tetracaine. Tetracaine is a potent ester used for surface anesthesia of the cornea. Tetracaine stings when placed in the eye, but only for 10 to 15 seconds, after which there is excellent corneal anesthesia.

Benzocaine. Almost insoluble in water, benzocaine remains on mucous membranes in the mouth and is commonly used to provide superficial analgesia for oral procedures and pain.

Agents Applied to Open Skin: Lidocaine, Epinephrine and Tetracaine. The combination of lidocaine, epinephrine, and tetracaine, 5 to 10 mL, may be applied to an open wound using sterile cotton, which is then covered and held in place for 10 to 20 minutes. Anesthesia has been described in approximately 85% of cases of wounds of the scalp and face and a lower percentage of extremity wounds. Application of the solution to mucous membranes (eye, intranasal) can result in toxic blood levels of tetracaine and should be avoided.

- Distraction techniques
Nonpharmacologic Interventions

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) systems use electrical stimulation to induce analgesia, likely through the activation of descending sensory pathways and modulation of nociceptive signals at the level of the spinal cord (Figs. 3.5 and 3.6). TENS units include a pulse generator, amplifier, and electrodes. Studies have demonstrated varying degrees of effectiveness. These devices are rarely indicated for use in the ED.

Hypnosis

The induction of hypnosis allows patients to refocus attention away from pain and anxiety-producing stimuli to other images and feelings. Hypnosis can be used as an adjunct to pharmacologic interventions or as a substitute. Hypnosis can be induced with only brief interventions on the part of the health care provider. Hypnosis is usually not practical in the ED due to time constraints and distracting ambient noise.

Out-of-Hospital Analgesia

Out-of-hospital providers frequently encounter patients with painful conditions. Patients obtain pain relief more quickly when pain medications are initiated by out-of-hospital personnel, although pain control in this setting is challenging to perform adequately.

KEY CONCEPTS

- Acute pain is an urgent condition for the patient. Pain should be rapidly assessed, treated, and frequently reassessed in tandem with diagnostic evaluations (see Fig. 3.7).
- Therapy for acute pain is different than for chronic pain (see Box 3.3). Chronic pain treatment should be undertaken in consultation with the provider(s) responsible for the patient’s long-term management. In general, opioid analgesic agents should not be administered in the ED or prescribed for outpatient therapy for chronic pain patients unless the plan is agreed to by the responsible outpatient provider.
- Titrated IV opioid analgesics are the principal therapeutic approach for the treatment of moderate and severe acute pain. When intravenous access is not indicated or attainable, SC administration is preferable to the IM route (see Box 3.5).
- Oral oxycodone, with an onset of action similar to that of IM or SC opioids, can be used for moderate pain when the IV route is not otherwise needed. Oxycodone and other oral opioids should be administered and prescribed as a single-drug preparation, not as part of a combination.
- Ambulatory treatment with opioids should be confined to the period of acute pain. Most opioid prescriptions from the ED for acute injury (eg, burn, fracture) should be for 3 to 5 days, after which the patient is transitioned to nonopioid analgesia or reevaluated by an outpatient provider.
- Acetaminophen and NSAIDs should be added to pain therapy, when not contraindicated. Their analgesic effects are additive to those of opioids and to each other.
- Morphine, fentanyl, and hydromorphone are the preferred parenteral opioid agents in the ED. Meperidine should not be used.
- There is no evidence to support the concept that diagnosis based on physical examination findings will be impaired by the administration of opioid pain medications to achieve reasonable patient comfort.
- There is no validity to the belief that morphine causes more smooth muscle spasm than other opioids. Morphine is safe and appropriate for patients with acute biliary or renal colic.
- Patients who are known to be diverting or abusing opioids should not be prescribed opioids for use as outpatients. Patients with chronic pain syndromes, or those with chronic conditions that may cause acute pain (eg, dental caries), should be offered alternative pain management options, and opioids generally should be avoided.
- Topical and local anesthetics can be used to treat pain associated with most ED procedures and should be considered for use in isolated painful conditions.
- Low tissue pH (5 or 6) in infected tissue impairs the effectiveness of local anesthesia.

The out-of-hospital environment is less controlled than the ED, and information regarding a patient’s underlying condition is more limited, making the safe administration of pain medications more difficult. As in the ED, establishing rapport with the patient, providing calm reassurance, and using careful movement and handling, including proper splinting, are the first steps to which pharmacologic support can be added. Pain can be assessed in the out-of-hospital setting using numeric and verbal rating scales, the same as would occur in the ED.

Protocols for the administration of fentanyl and morphine are available in most emergency medical services systems and are usually limited to single-dose therapy prior to obtaining orders from the medical control physician. Morphine, 0.1 mg/kg, is safe for out-of-hospital use and should be considered the first-line agent for severe pain, as it is in the ED. There is no difference in the relative value of using fentanyl or morphine as the initial agent for prehospital pain treatment.

OUTCOMES: TREATMENT ENDPOINTS

Pain is a subjective experience. In the ED, management of acute pain should specify an initial dose, with a repeat dose and interval determined through a specific desired endpoint, such as pain reduction measured by a standardized assessment tool (see Fig. 3.7). A reasonable endpoint is to achieve sufficient pain relief for the patient to be able to doze or carry on a normal conversation with providers or family members.

CHAPTER 3: QUESTIONS & ANSWERS

3.1. Which of the following statements is true regarding pain transmission?
A. Cardiac pain is transmitted via the sympathetic system.
B. Central poststroke neuropathic pain is associated with parietal infarcts.
C. Descending modulation of pain is mediated primarily through γ-aminobutyric acid (GABA).
D. Peripheral neurotransmitters include prostaglandins, histamines, and substance P.
E. The dorsal columns play no role in pain transmission.
Answer: A. As a general rule, all visceral pain is carried via sympathetic afferents to ganglia and then to the spinal cord. Prostaglandins, substance P, and histamine sensitize peripheral afferents but are not neurotransmitters. The dorsal columns transmit down-modulate ascending pain signals. Central poststroke pain is clinically seen most often after thalamic strokes. Descending tracts that modulate pain processing at the dorsal horn use norepinephrine and serotonin, with the effect of the former being most important regarding analgesia.

3.2. Which of the following analgesics is matched with the correct feature?
A. Fentanyl—prolonged QT interval on electrocardiography
B. Hydromorphone—active metabolites
C. Meperidine—muscle rigidity
D. Oxycodone—serotonin syndrome
E. Propoxyphene—anticholinergic toxicity
Answer: D. Oxycodone has been associated with serotonin syndrome when coadministered with selective serotonin reuptake inhibitor (SSRI) medications. The following are the other correct associations:
Meperidine—anticholinergic toxicity, active metabolites
Propoxyphene—prolonged QT interval on electrocardiography
Fentanyl—muscle rigidity (chest wall)
Hydromorphone—inactive metabolite
3.3. A 32-year-old male patient undergoing treatment for an ankle sprain returns to the emergency department (ED) because of inadequate pain relief from the medicines he was prescribed. He is currently taking oxycodone, 10 mg PO every 4 hours, and ibuprofen, 400 mg every 4 hours. What is the next most appropriate medicine to add to his pain treatment regimen?

A. Add acetaminophen, 650 mg q4h.
B. Add tramadol, 50 mg PO q4h.
C. Increase ibuprofen to 800 mg.
D. Increase oxycodone to 15 mg.
E. Replace oxycodone with hydrocodone, 15 mg PO q4h.

Answer: A. Acetaminophen provides additive analgesia to nonsteroidal antiinflammatory drugs (NSAIDs) and opioids, with few adverse effects at low doses, and it should be incorporated in acute pain treatment when not contraindicated. The pain-relieving effects of ibuprofen have not been shown to be greater when 800 mg is used versus 400 mg, so increasing the dose of ibuprofen is unlikely to improve pain relief and will increase the risk of adverse effects of the NSAIDs. An increased dose of oxycodone would result in improved pain relief but increases the risk of adverse effects; it should be tried after other nonopioid treatments have failed. In this case, acetaminophen should be attempted first before increasing the oxycodone dose. Tramadol may improve pain relief and would be additive to the opioid effect of the oxycodone but would not be indicated before acetaminophen because of its high rate of dizziness and nausea. The pain-relieving effects of opioids at equianalgesic doses usually do not vary among individuals, and switching from an equivalent dose of one opioid to another is unlikely to improve pain treatment. Changing to hydrocodone, therefore, would be unlikely to decrease the patient’s pain.
CHAPTER 4
Procedural Sedation and Analgesia

Steven A. Godwin

PRINCIPLES

Background
The performance of diagnostic and therapeutic procedures is common in emergency care. Many of these interventions are often associated with significant pain and anxiety. Procedural sedation and analgesia (PSA) is a fundamental and required skill for emergency clinicians and an integral part of the core training of emergency medicine residents.

Chapter 162 will provide specific guidance for PSA for children. PSA improves the quality of patient care and satisfaction through the relief of pain and anxiety and by facilitating timely and successful therapeutic or diagnostic procedures. These include fracture or joint reduction, incision and drainage of abscesses, cardioversion, tube thoracostomy, lumbar puncture, complex wound repair, and imaging studies in uncooperative patients.

Many of the agents used for PSA have the potential to cause significant respiratory, cardiovascular, or central nervous system (CNS) depression. The Joint Commission (TJC), Centers for Medicare and Medicaid Services (CMS), American College of Emergency Physicians (ACEP), and American Society of Anesthesiologists (ASA) have produced expert consensus and evidence-based guidelines concerning the use of PSA. Although controversy continues about credentialing and oversight of PSA outside the operating room at some individual institutions, the advent of these guidelines has led to PSA becoming a common ED procedure. The adoption of PSA as a standard procedure in the ED has been further enhanced by the availability of shorter acting, more effective drugs and noninvasive monitoring devices.

With the wide variety of patient populations and procedural needs, the ability to individualize PSA for each unique situation is a necessary skill. This can be best achieved through a detailed understanding of the preprocedural patient assessment, protocols delineating the required personnel and their roles, supplies and equipment required, specific drugs used (including their routes of administration, dosages, effects, interactions, and complications), consideration for special populations, and patient monitoring, recovery, and discharge criteria.

Terminology
The following terms are important for understanding the concepts presented in this chapter:

Anxiolysis is a state of decreased apprehension concerning a particular situation in which the patient’s level of awareness does not change. Analgesia refers to the relief of pain without the intentional alteration of mental status, such as occurs in sedation. An altered mental state may be a secondary effect of the medications administered for this purpose.

Dissociation is a trancelike cataleptic state induced by an agent such as ketamine and characterized by a profound analgesia and amnesia. Protective reflexes, spontaneous respiration, and cardiopulmonary stability are retained. Sedation is a controlled reduction of environmental awareness.

Procedural sedation and analgesia is a technique of administering a sedative or dissociative agent, usually along with an analgesic, to induce a state that allows the patient to tolerate painful procedures while maintaining adequate spontaneous cardiopulmonary function. It is intended to result in a depressed level of consciousness that allows the patient to maintain oxygenation and airway control independently and continuously. The drugs, doses, and techniques used are not likely to produce a loss of the protective airway reflexes.

In 2001, TJC adopted the ASA definition of sedation and analgesia that was created to describe the continuum of sedation and analgesia better (Fig. 4.1). Although this actually is a continuum, the ASA has divided PSA into four distinct subgroups—minimal sedation, moderate sedation, deep sedation, and general anesthesia. A fifth category, dissociative sedation, has since been added (Table 4.1). This new nomenclature is more intuitive, clear, and logical.

Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive functions and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate sedation and analgesia (formerly called conscious sedation) refers to a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, alone or accompanied by light tactile stimulation. Reflex withdrawal from the painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is always maintained.

Dissociative sedation is a trancelike cataleptic state induced by the dissociative agent ketamine; it is characterized by profound analgesia and amnesia while protective airway reflexes, spontaneous respirations, and cardiopulmonary stability are maintained.

Deep sedation and analgesia describes a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to maintain ventilatory function independently may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even with painful stimulation. The ability to maintain ventilatory function independently is often impaired. Patients often require assistance in

52
Fig. 4.1. Schematic representation of the sedation continuum. As increasing doses of nondissociative agents are given, patients move along the sedation continuum, experiencing a progressive decline in their level of consciousness and an increased risk of adverse respiratory and cardiovascular events. If medication administration continues, the patient will ultimately reach a state of general anesthesia, with loss of protective airway reflexes and ventilatory drive. The transition from one level of sedation to the next is often difficult to predict and varies from patient to patient.

### BOX 4.1

**American College of Emergency Physicians Policy Statement on Sedation in the Emergency Department**

The American College of Emergency Physicians recommends the following:

- Emergency clinicians who have received the appropriate training and skills necessary to safely provide procedural sedation should be eligible for credentialing in all levels of procedural sedation.
- The decision to provide sedation and selection of the specific pharmacologic agents should be individualized for each patient by the emergency clinician and should not be otherwise restricted.
- Emergency clinicians and staff are expected to be familiar with the pharmaceutical agents they use and be prepared to manage their potential complications.

- To minimize complications, the appropriate drugs and dosages must be chosen and administered in an appropriately monitored setting, and a patient evaluation should be performed before, during, and after their use.
- Institutional and departmental guidelines related to the sedation of patients should include credentialing and verification of competency of providers, selection and preparation of patients, informed consent, equipment and monitoring requirements, staff training and competency verification, criteria for discharge, and continuous quality improvement.

---

*January 2011.
Adapted from American Society of Anesthesiologists Committee: Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. Anesthesiology 114:495–511, 2011.

---

maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

The progression from minimal sedation to general anesthesia is a dynamic continuum that lacks distinct separation between stages. The transition from one level of sedation to the next is often difficult to predict and varies from patient to patient. The sedation continuum is not drug-specific, and levels from mild sedation to general anesthesia can be achieved with virtually all the PSA agents. Because of this, it is recommended that emergency clinicians administering PSA be competent in the skills required to treat patients who are in at least one level greater than the intended level of sedation.

**Management**

**Decision Making**

The approach to undertaking procedural sedation requires a diligent evaluation of a patient’s specific conditions, which may
PART I

Evidence supporting the practice of preprocedural fasting, need for appropriate personnel, supplies, and equipment, patient monitoring, and postprocedural recovery.

**Patient Assessment.** Although no outcome-based studies have demonstrated a clear benefit from premedication evaluation beyond vital signs, mental status, and airway and cardiopulmonary assessment, consensus guidelines have suggested that there may be an increased risk of adverse events in select subsets of patients. These include patients at the extremes of age, patients with difficult facial or neck anatomy or any other reason for potential intubation or bag-valve-mask ventilation difficulty, and patients with underlying significant disease states. A patient’s general physical status is conventionally categorized according to the ASA’s classification system (Table 4.2). Most practice guidelines require that a history and focused physical examination be performed and documented before PSA. There have been no studies to support the need for routine diagnostic testing other than diagnostic testing driven by the patient’s current status, including comorbidities.

The patient’s age, current illness, or injury for which PSA is intended, underlying medical problems (eg, comorbidities), previous experiences or problems with PSA or general anesthesia, drug allergies and current medications, and tobacco, drug, and alcohol use are reviewed and recorded. A directed physical examination focuses on the vital signs, heart and lungs, and evaluation of the airway for potential difficulty providing bag-valve-mask ventilation or intubation.

A discussion including the risks, benefits, and potential side effects of PSA should be held with patients or their families before the procedure. Written consent is preferred, unless this is not possible due to issues related to the patient’s clinical condition or access to the patient’s medical surrogate. Not every patient is an appropriate candidate for PSA in the ED. Therefore, patient selection is important to the safety of the sedation. Depending on the clinical circumstances, a patient with an anticipated difficult airway or ASA classification of III or IV may require support of additional clinical resources. These resources can include additional nursing support or additional providers with expertise in procedural sedation, including emergency clinicians and/or anesthesiologist. At times, it may even be advisable to undertake the procedure under more controlled circumstances in the operating room with anesthesia.

**Preprocedural Fasting.** Evidence supporting the practice of preprocedural fasting in PSA has been extrapolated from patient populations undergoing general anesthesia. To date, there have been no published outcome-based studies demonstrating an increased risk of aspiration after a liquid or solid meal and no studies showing a benefit of fasting before PSA. Despite the absence of literature to support this practice and its inevitable negative impact on timeliness of patient care and diagnosis, disagreement still exists as to how these societal guidelines are implemented at individual centers.

Currently, for healthy patients undergoing elective procedures, the ASA recommends a period of 2 hours after ingestion of clear liquids, 4 hours after ingestion of breast milk, and 6 hours after ingestion of other liquids (eg, infant formula, nonhuman milk) or solids before PSA. Importantly, emergent sedations are noted as an exclusion from the fasting requirements within the framework of these same guidelines. The extrapolated data from studies describing cases in which patients received sedation to the level of general anesthesia, followed by the manipulation of the airway during intubation and extubation, are not generalizable to the ED setting. PSA in the ED attempts to avoid both these specific situations.

In 2013, ACEP endorsed a level B recommendation—defined by the level of graded evidence equating to a moderate degree of certainty—regarding preprocedural fasting stating. It stated that providers should not delay procedural sedation in adult or pediatric patients in the ED based on fasting time. The recommendation further noted that preprocedural fasting for any duration has not demonstrated a reduction in the risk of emesis or aspiration during procedural sedation and analgesia. Food intake should therefore not be considered a contraindication for administering PSA in the ED. Providers should consider the unique clinical and physiologic circumstances of each individual patient to identify challenges specific to that patient’s needs.

**Personnel.** TJC and most institutional policies have suggested that PSA providers should have adequate training to administer the agents effectively and safely. This includes the skill to assess risk, dose, and administration of medications appropriately, monitor the patient’s response to the medications given, and manage all potential complications. This generally implies that PSA in the ED should be supervised by an emergency clinician or other appropriately trained and credentialed physician. It is also recommended that a qualified support person (eg, nurse, respiratory therapist) be present for continuous monitoring of the patient. Such a support person should focus on the patient’s status and not take part in the procedure. He or she should also be able to recognize and respond to the complications of PSA. Although it is acceptable that they may also assist with minor interruptible tasks, they should have no other primary responsibilities that would interfere with the monitoring and documentation appropriate for the planned level of sedation from the start of the procedure to completion of the recovery phase.

**Supplies and Equipment.** PSA may result in an allergic reaction, oversedation, respiratory depression or, rarely, cardiovascular arrest. The incidence of these complications depends on patient selection, drugs used, rate and dosage of administration, and specific patient sensitivities. Consequently, appropriate equipment to monitor the patient’s condition at all times, manage...
The requirement for supplemental oxygen, and its benefits during PSA, have not been well studied and remain somewhat unclear. Supplemental oxygen may prevent hypoxemia in many patients; however, significant respiratory depression in these patients may not be detected because of their normal oxygen saturation. This may delay the recognition of respiratory compromise and hypercarbia when capnography is not used. On the other hand, transient hypercarbia is not harmful, and maintenance of adequate oxygen saturation is much more important. The use of capnography eliminates this issue, because ventilatory status is adequately oxygen saturation is much more important. The use of capnography can significantly reduce hypoxemic events during procedures. Evidence has demonstrated that the use of capnography can significantly reduce hypoxemic events during procedures.

In 2014, ACEP endorsed a level B recommendation that capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing procedural sedation and analgesia in the ED. It is also recommended by the American Society of Anesthesiologists for monitoring the presence of exhaled carbon dioxide during moderate or deep sedation, in addition to the continual observation of qualitative clinical signs of adequate ventilation. ECG, Electrocardiogram.

Monitoring Devices and Techniques. The most important aspect of monitoring during PSA is the visual observation and assessment of the patient. The patient’s ability to follow commands in response to varied levels of stimulation is useful in quantifying the level of consciousness. Furthermore, the patient’s ventilatory rate may be readily assessed by direct observation, although depth of respiration or tidal volume is actually much harder to estimate clinically. Other components of monitoring, which should be documented, include determination of respiratory rate, heart rate, blood pressure, oxygen saturation, and cardiac rhythm and capnometry. Pulse oximetry is a reliable and important monitoring modality, used in conjunction with close and continuous observation of the patient and his or her response to medications and procedures.

Although there is no outcome-based evidence that cardiac monitoring during PSA is of any benefit, it certainly is not harmful, is routinely available, and may be beneficial in certain cases. I recommend continuous electrocardiographic monitoring in older patients and in patients with a history of cardiovascular disease, hypertension, or dysrhythmia. In young healthy patients, without underlying significant disease, this may be safely replaced by continuous pulse oximetry, which also displays the heart rate but, in most cases, monitors capable of showing heart rate, blood pressure, and pulse oximetry will also easily facilitate cardiac rhythm monitoring.

Capnometry or capnography measures end-tidal carbon dioxide (CO₂) partial pressure and has been shown to detect cases of inadequate ventilation earlier than clinical assessment or detection of hypoxemia by oximetry. Evidence has demonstrated that the use of capnography can significantly reduce hypoxemic events during procedures. In July 2011, the ASA updated its procedural sedation standards to include capnography during moderate or deep sedation to evaluate the adequacy of ventilation in addition to continual observation of qualitative clinical signs. In 2014, ACEP endorsed a level B recommendation that capnography may be used as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing procedural sedation and analgesia in the ED.

We recommend that continuous capnography be used when deep sedation is planned, because respiratory depression is common in patients undergoing deep sedation. Although optional when only light sedation is planned, capnography may enhance patient safety by allowing the observer to recognize unintended oversedation and depression of respiratory rate or volume more rapidly.

The bispectral index (BIS) is monitored via a noninvasive device attached to the patient’s forehead and determines the depth of sedation level via frontal lobe electroencephalographic measurements. It has been used in the operating room as an objective measure of sedation depth. Studies have hypothesized that its use may be beneficial in preventing oversedation in PSA and reducing the time to discharge. Early ED studies for its use in PSA to discriminate between mild to moderate and moderate to deep levels of sedation have not demonstrated a reliable advantage, nor has it been shown to be predictive of patients sedated to the point of general anesthesia as differentiated from those with lesser degrees of sedation. BIS monitoring has yet to demonstrate a beneficial role for emergency medicine use for routine PSA monitoring. Future studies, combined with advancement of current technology, may better define its potential role.

When transporting patients outside the ED for diagnostic procedures requiring PSA, every attempt should be made to provide the same level of monitoring during the transport and procedure as would be used within the department.

The highest risk of serious adverse events generally occurs within 5 to 20 minutes of receiving the last dose of IV medication and at the completion of procedures, when the patient remains sedated but is no longer receiving the painful stimulus. Similarly, patients undergoing prolonged procedures in which deeper sedation is desired to reduce motion (eg, magnetic resonance imaging [MRI]) are also at an increased risk. Patients should continue to be monitored closely at these times, and this should continue until clinical recovery has occurred.

Recovery. Monitoring as part of the PSA routine should continue until patients are spontaneously awake and able to function independently. Drowsy patients should not be left unattended, and appropriate measures to prevent falls should be taken.

**BOX 4.2**

**Equipment for Procedural Sedation and Analgesia**

- High-flow oxygen source
- Suction
- Airway management equipment
- Monitoring equipment
  - Pulse oximeter
  - ECG monitor, defibrillator, transcutaneous pacemaker
  - Blood pressure monitor
  - Capnography
  - Vascular access equipment
  - Reversal agents
  - Resuscitation drugs
  - Adequate staff

*Capnography carries a level B recommendation by the American College of Emergency Physicians for use as an adjunct to pulse oximetry and clinical assessment to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in patients undergoing procedural sedation and analgesia in the ED. It is also recommended by the American Society of Anesthesiologists for monitoring the presence of exhaled carbon dioxide during moderate or deep sedation, in addition to the continual observation of qualitative clinical signs of adequate ventilation. ECG, Electrocardiogram.*
**Postprocedure Recovery and Discharge.** Before discharge, baseline cognitive and motor functions should be achieved. The patient should be able to follow commands, speak clearly, and ambulate or sit unassisted (infants and children). Vital signs and respiratory status should be back to baseline and within normal limits. Residual pain should be addressed. Nausea should be minimal, and vomiting should be resolved. It is preferable that all patients, including adults, be sent home with a responsible adult but, if this is not possible, the patient should remain in the ED until a normal baseline has been achieved.20,37

Patients should be advised not to drive or participate in other dangerous activities for 12 to 24 hours. Despite the short clinical duration of most of the agents used, some patients may exhibit subtle signs of cognitive deficits and mild drowsiness. It is therefore preferable that they remain in the company of a responsible adult at home for 4 to 8 hours. For children, light play at home should be the extent of activities, with no bicycle riding, swimming, or other complex motor activity until the next day. An antiemetic and progressive diet is helpful if nausea or vomiting is experienced. Standard discharge instructions should also be provided for the presenting complaint, and all patients should be instructed to immediately return if any confusion or respiratory symptoms arise.

**Pharmacologic Therapy**

In selecting agents, consideration is given to the effects desired, risks and benefits, and logistics of administration for each situation. Unfortunately, the ideal agent does not exist. It would need to provide analgesia, anxiolysis, amnesia, and somnolence. The provider should have a clear understanding of the purpose and priorities of PSA so she or he can relate it to the procedure being performed. When the procedure is unpleasant but not painful (eg, endoscopy), pure sedation may be the desired endpoint, and agents such as benzodiazepines, barbiturates, etomidate, or propofol are sometimes used alone. These agents do not provide pain relief and should not be used as the sole agent when pain management is also desired. Analgesic agents such as opioids or nitrous oxide are often added to a sedative agent to provide analgesia for painful procedures. In contrast, ketamine, as a dissociative agent, may be an excellent single drug choice for painful or stimulating procedures in children and for some adult applications (eg, fracture reduction). Usually, a combination of analgesic and sedative agents is required. Caution is indicated, however, because their side effects are frequently potentiated.

The specific agents for PSA and dosage recommendations for adult patients are provided in Table 4.3. Their benefits and adverse effects are provided in Table 4.4. Individual agents are discussed in greater detail in the following sections.

**Routes of Administration.** The decision regarding the optimal route of administration should be determined by the procedure and requirements of the specific patient. In general, IV titration to the desired level of sedation and analgesia produces the most rapid, safest, and predictable results. Drugs given by the intramuscular (IM), oral, transmucosal, intranasal, or rectal route generally have a slower onset of action, are difficult to titrate, have unpredictable results, and may lead to prolonged sedation. These routes are rarely used for PSA in adults. In pediatric patients, however, the benefits of IV drug administration may be outweighed by the difficulty and distress to the patient in obtaining IV access. In this situation, drugs given by the alternative routes may be preferred (see Chapter 162). For example, ketamine has been shown to provide consistent and predictable results in children when given IM.37,38 The use of nitrous oxide is limited to pediatric patients and special circumstances and is not fully

CV, Cardiovascular; HR, heart rate; ICP, intracranial pressure; IOP, intraocular pressure.

discussed in this chapter. It has a predictable behavior when used as a sole inhalational PSA agent in children but is also frequently used as an analgesic adjunct to a sedating agent.39

Drugs should be administered by titrated slow IV bolus to minimize hypotension or respiratory depression in many situations. It is important to allow adequate time between doses to achieve and assess peak effect before an additional dose is given. Lower initial doses should be chosen in sensitive patients or when drugs from multiple classes are being administered. Ketamine is considered the exception because, unlike the other agents described, it possesses a threshold response rather than an additive dose-response continuum. Smaller doses of ketamine cause analgesia and disorientation. Dissociation occurs when a dosage threshold of 1 to 1.5 mg/kg IV in adult patients or 1.5 to 2.0 mg/kg in younger pediatric patients is reached. Higher doses have not been shown to enhance or deepen the sedation.

Opioids. Parenteral opioids are commonly used as analgesics before painful procedures are performed. For PSA, an opioid is rarely optimal as a single agent, and most emergency clinicians
combine an opioid with a sedative-amnestic agent to balance sedation-amnesia and analgesia with the least likelihood of respiratory depression. One preferred method of establishing adequate analgesia for a painful procedure when using combined agents is addressing the pain requirements initially in the medication sequencing and then adding the anxiolytic for sedation. The most commonly used opioids in the ED for PSA are fentanyl and morphine. These are often combined with benzodiazepines such as midazolam for moderate sedation and are used in smaller doses to provide analgesia during deep sedation with etomidate or propofol. Meperidine historically was used for PSA but is no longer recommended because seizures are commonly associated with the accumulation of its long-lasting metabolite, normeperidine.

**Fentanyl.** Fentanyl has many advantages as an analgesic agent for PSA, given its rapid onset of action, short duration of activity, lack of histamine release, and favorable cardiovascular profile. Fentanyl rapidly crosses the blood-brain barrier and produces analgesia in as little as 90 seconds. Serum levels rapidly decline from peak concentrations because of extensive tissue uptake followed by hepatic metabolism. It has a duration of action of 30 to 40 minutes; the peak respiratory depressant effect of a single IV dose of fentanyl is 5 to 15 minutes following injection. These properties permit the titration of multiple small doses to the desired clinical effect. Because fentanyl readily creates a reservoir in adipose tissue, accumulated large doses may result in a progressively increasing duration of effect. This does not generally occur in doses less than 10 µg/kg. For deep sedation, a single dose of 1 to 2 µg/kg of fentanyl is often given before the sedating agent. After adequate pain relief has been achieved, a smaller dose of a sedative agent may then be added and titrated to effect. Respiratory depression is minimized in this fashion. For moderate sedation, fentanyl can be titrated, along with a sedative agent such as midazolam, depending on whether the emergency clinician thinks that more sedative effect (midazolam) or analgesic effect (fentanyl) is required. Dosage should begin at 1 µg/kg and be slowly titrated upward every 1 to 2 minutes, until the desired level of analgesia has been achieved. Sufficient analgesia for painful procedures under moderate sedation usually is accomplished with doses of 2 to 3 µg/kg and under deep sedation with 1 to 2 µg/kg. Lower doses should be used in older patients or when other CNS depressants have been previously administered (eg, ethanol).

Respiratory depression is more likely at higher doses, when the drug is given rapidly, or when it is combined with other CNS depressants, such as benzodiazepines or alcohol. Other side effects may include vomiting and pruritus, although these are less common than with other opioids. Hypotension and bradycardia are rare but may occur with high doses. These adverse effects may be readily reversed by naloxone. Chest wall rigidity and glottic spasm, which may make ventilation difficult, are unique complications seen with high doses (anesthetic) of fentanyl not used for PSA and when given rapidly (generally > 7 µg/kg). In the rare event of chest wall rigidity, symptoms may not reliably be antagonized by naloxone and may necessitate neuromuscular blockade and intubation to enable adequate ventilation.

**Morphine.** Morphine is poorly lipid-soluble and penetrates the blood-brain barrier more slowly after small bolus injections. A period of 10 to 30 minutes is required before its peak effects are seen although, when used for PSA, morphine performs in a similar fashion to fentanyl, with comparable recovery times. A general starting dosage of 0.1 mg/kg is commonly used and then titrated to desired effect, as with fentanyl. Morphine has much more histamine release and therefore is more likely to produce hypotension, especially in preload-dependent patients. This fact, combined with its slow peak onset time, make it a less ideal opioid for use in PSA. It has a similar potential as other opioids for producing respiratory depression, especially when used with other CNS depressants, such as benzodiazepines. Morphine undergoes hepatic metabolism to an active metabolite, followed by renal excretion. Insufficiency of either organ system may lead to increased serum half-life.

**Benzodiazepines.** Benzodiazepines are potent amnestic, hypnotic, and anxiolytic medications. They also have anticonvulsant and muscle relaxant properties but do not have analgesic effects. Because of this, they are commonly coadministered with an analgesic agent, such as fentanyl or morphine. They may be given IV, IM, via the oral (PO) or intranasal (IN) route or per rectum (PR) but are virtually always used via the IV route for PSA in adults. Midazolam is the most commonly used agent because of its favorable pharmacokinetics.

**Midazolam.** Midazolam has many advantages for PSA, given its rapid onset of action and short duration of action compared with other benzodiazepines. Its stronger amnestic properties are an added advantage to other benzodiazepines. The starting IV dose is 0.05 mg/kg. Children may need slightly higher doses. The onset of sedation is generally within 1 to 2 minutes, and the duration of action is 30 to 60 minutes. Alternatives to the IV route are often used in children, including IM, PR, IN, and PO routes. Midazolam has been shown to be an extremely safe and effective agent for PSA, both alone and when used in combination with fentanyl.

Side effects include dose-dependent hypoventilation and hypoxemia. Apnea and hypotension are uncommon but occur more often at high doses or when other CNS depressants, such as opioids, are used. Headache, nausea, emesis, coughing, and hiccups have been shown to occur, although rarely. Lower doses should be used when other agents such as analgesics are given concomitantly or given to older adults. Prolonged effects may be seen in older adults or those with liver dysfunction owing to decreased hepatic or first-pass metabolism. Midazolam is highly lipophilic, and its effects may be greatly amplified in obese patients, resulting in an increased plasma half-life of up to 8 hours with high or repetitive doses. Chronic alcohol users who do not have liver dysfunction may require relatively high doses of midazolam to achieve the same clinical effects as a result of cross-tolerance.

**Barbiturates.** Barbiturates are also potent hypnotics, with amnestic and anticonvulsant effects. They do not have analgesic properties. Therefore, the barbiturates pentobarbital, thiopental, and methohexital have been more commonly used for brief painless procedures. Methohexital has been combined with an analgesic for use in orthopedic procedures. However, because these agents have been replaced with other better tolerated and titratable short-acting agents, we do not recommend the routine use of barbiturates for procedural sedation in adults; see Chapter 162 for a discussion of their indications in children.

**Ketamine.** Ketamine is a well-studied, safe, and predictable agent for use in the pediatric population for PSA. Immediately, it has also gained popularity for use in adults for PSA. It is a derivative of the street drug phencyclidine and is classified as a dissociative agent. It causes disruption between the thalamocortical and limbic systems, preventing the higher centers from perceiving visual, auditory, or painful stimuli. Because of this, ketamine leads to profound analgesia, amnesia, and catalepsy. It does not produce unconsciousness, but rather a trancelike state. Patients often experience nystagmus, roving eye movements, and random movements of the extremities, unrelated to painful stimuli. Parents who observe a procedure in which ketamine is used may be disturbed at seeing this and should be forewarned.

Ketamine has several advantages over other PSA agents. The most notable are its profound analgesic effect and lack of
significant respiratory depression. The protective airway reflexes, such as coughing, swallowing, and muscular tone of the tongue and pharynx, are preserved or slightly enhanced. Its use further leads to blockade of catecholamine reuptake, and blood pressure is generally well supported. It also induces bronchial smooth muscle relaxation and is well tolerated in patients with reactive airway disease. It has a fast onset and offset and is predictable when given by the IV or IM route. After administration, it is rapidly distributed and taken up by the cerebral tissues. The effects are maintained until the drug redistributes into the peripheral tissues and is metabolized by the liver. As a result, repeat doses are well tolerated in longer procedures. However, emergency clinicians should be aware that this might lead to longer recovery times and increased incidence of emesis.

Ketamine may be given by multiple routes but is administered almost exclusively by the IV route in adults. After an IV dose of 1 to 2 mg/kg, a dissociative state results in approximately 1 minute, with duration of action of approximately 15 minutes. Complete recovery generally requires 1 to 2 hours. Similar cataleptic results may be seen with IM administration of 4 to 5 mg/kg in approximately 5 minutes, with effects lasting 15 to 30 minutes. For pediatric sedation, ketamine is generally administered by the IV or IM route but may also be given via the PO, PR, or IN route. These other routes are infrequently used because of variable onset of action, slow offset, and less predictable results.

The most common side effect seen with ketamine is the emergence phenomenon. This occurs in approximately 15% of patients and is typically a mild reaction. The patient awakens with unpleasant vivid dreams or hallucinations or reports nighttime awakenings as a result of unpleasant dreams for several days after the administration of ketamine. Less than 1% to 2% of patients have significant emergence agitation. This is more commonly seen in female patients, adolescents, or adults and in those with underlying psychiatric disorders. Its rare occurrence, especially in children, should not limit the use of ketamine when indicated. Some have previously suggested concurrent administration of midazolam to mitigate this reaction, but studies have failed to support this practice, and the most recent clinical practice guideline updates do not recommend this practice in children. The routine concomitant use of a benzodiazepine when administering ketamine sedation is therefore not recommended, unless it is judged to be of benefit for preprocedural anxiety. Benzodiazepines are useful for treating an emergence phenomenon if it occurs during the recovery phase. Emesis is the most common side effect, and concomitant dosing with a benzodiazepine and an antiemetic has been shown to reduce its incidence. Other side effects seen with ketamine use during sedation include transient apnea and laryngospasm. These are also rare but have been suggested to be more common with rapid IV administration or with larger doses. Doses given slowly, at a rate of 0.5 mg/kg/min, may further limit these events. Ketamine also stimulates tracheobronchial and salivary secretions. In any patient undergoing airway examination (eg, fiberoptic laryngoscopy), pretreatment with glycopyrrolate, 0.01 mg/kg given 10 minutes before the ketamine, may be beneficial. Because airway reflexes are maintained, this generally is not a concern in other patients. Prophylactic pretreatment with anticholinergics is unnecessary, and this practice is no longer recommended. Postrecovery nausea and vomiting are also frequently seen but are generally short-lived and respond well to typical antiemetics, such as ondansetron.

Because of the potential for catecholamine-mediated hypertension and tachycardia, ketamine should also be avoided in those with significant cardiovascular or coronary artery disease. Ketamine also increases intraocular pressure and should be avoided in those with open globe injuries. Ketamine is contraindicated in patients with psychosis, even when well controlled.

**Sedative-Hypnotics**

**Etomidate.** Etomidate is a short-acting, sedative-hypnotic agent that is structurally unrelated to the other PSDA agents and has no analgesic properties. Its use leads to the very rapid onset of profound sedation and hypnosis by enhancing neurotransmission at γ-aminobutyric acid (GABA) receptors. Etomidate has been used for deep sedation because of its rapid onset, short duration of action and, most importantly, minimal effects on respiratory and cardiovascular function.

After IV administration, sedation occurs in approximately 1 minute, and patients recover in 5 to 10 minutes. Etomidate induces deep sedation that borders on general anesthesia with higher doses and may be more difficult to titrate than the other sedative-hypnotics. It is generally administered IV, with an initial dose of 0.1 mg/kg given slowly over 1 to 2 minutes. Additional doses of 0.05 to 0.1 mg/kg may be administered every 2 to 3 minutes until the desired level of sedation has been achieved. Smaller initial doses should be considered when etomidate is combined with analgesic agents or given to older adults. Because it has little effect on the cardiovascular system and is cerebroprotective, it is an excellent choice for patients who have the potential for the development of hemodynamic instability or increased intracranial pressure.

Adverse effects that may limit its usefulness include apnea, respiratory depression, myoclonus, nausea, vomiting, and adrenal suppression. These side effects are more common with rapid IV administration, when higher doses are used, and in older patients. Myoclonus is the most common side effect and is typically described as mild and brief but, at times, may be severe enough to interfere with the procedure. Although respiratory depression is rare and generally transient, few patients may require brief periods of assisted ventilation. Vomiting is unlikely with doses administered in the ED. Etomidate suppresses adrenal function by inhibiting 11-β-hydroxylase activity. Although some debate exists, this is generally not clinically relevant with a single sedating dose.

**Propofol.** Propofol is another ultra-short-acting sedative-hypnotic that is structurally unrelated to the other PSDA drugs and has no analgesic properties. It has an extremely rapid onset, short duration of action, and predictable efficacy for inducing deep sedation.

Sedation quickly clears completely, permitting superior titration and earlier recovery and discharge. Propofol also possesses potent antiemetic properties and decreases intracranial pressure. Because of its properties, propofol is a highly desirable and widely used agent for deep sedation in the ED. It does not provide analgesia, however, and should be preceded by an opioid for painful procedures. As with all sedative agents, the addition of an opioid may increase the risk of deeper than anticipated sedation, respiratory depression, apnea, and hypotension, and smaller starting doses are recommended.

Propofol is administered with an initial IV bolus dose of 0.5 to 1 mg/kg that is then titrated every 1 to 3 minutes by 0.25- to 0.5-mg/kg aliquots to the desired sedation level. Children may require slightly higher weight-adjusted doses than adults. The onset of sedation occurs in less than 1 minute, and patient recovery occurs in 10 minutes. For procedures lasting longer than this, additional boluses of 0.5 mg/kg may be administered, or a continuous infusion of 3 to 6 mg/kg/hour may be titrated to the desired level of sedation. Smaller doses should be used when sedating older patients or when administering propofol to patients pretreated with analgesics.

Adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Other agents, such as opioids, may intensify these effects. In most cases, apnea is

---

*References 3, 4, 7, 9, 21, 43, 54, and 55.*
transient, and patients will not experience a significant decrease in their oxyhemoglobin level before recovering their respiratory function. This underscores the value of supplemental oxygen administration during sedation. If the oxygen saturation decreases to the low 90s, the patient may require a brief period of assisted ventilation. Propofol commonly results in a transient decrease in systolic and diastolic blood pressures, which rarely necessitates fluid administration and is well tolerated by healthy patients. The hypotensive effect is exaggerated in older adults and in patients with hypovolemia, and the initial dose of propofol should be reduced to 0.25 to 0.5 mg/kg in such patients. Pain associated with propofol injection occurs in most patients and can be reduced with small infusions of IV lidocaine before its administration. Despite these concerns, propofol has been shown to be reliable and safe when used with proper monitoring in the ED setting.

**Ketamine Plus Propofol.** Ketamine is commonly combined with propofol (known as ketofol) for PSA; although originally studied in children, its use has been expanded to adults. The two completely different agents are thought to have synergistic effects that balance each other's deficits while decreasing the overall dose of propofol. Ketamine provides the analgesic effects that propofol lacks. Furthermore, ketamine's cardiorespiratory stimulating effects provide a balance to the respiratory depression and hypotension caused by propofol. Also, vomiting and recovery hallucinations from ketamine are potentially mitigated by the antiemetic and hypnotic effects of propofol.

In several recent studies, ketofol was not shown to be clinically superior to either agent used alone with regard to respiratory depression or airway complications. There was statistically significant benefit in provider satisfaction, sedation quality, and decreased emesis and a clinically insignificant improvement in recovery time. Patients receiving ketofol frequently require less redosing due to the extended effects of the ketamine to maintain a similar depth of sedation. Although the use of this combination is extremely popular, it cannot be currently recommended as superior to propofol, propofol plus fentanyl, or ketamine, with or without ondansetron.

**Ultra—Fast-Acting Agents.** Reports and studies addressing agents such as alfentanil and remifentanil in PSA in the ED are limited. Alfentanil is an ultra—short-acting analogue of fentanyl that has been described for PSA in the ED. This agent has been used in anesthesia and has also been found to be safe and effective when added to propofol for PSA in the ED. Emergency clinicians should be aware that patients who receive supplemental alfentanil may require additional stimulation to induce ventilation during ED PSA and may have extended recovery periods. Although alfentanil is safe when added to propofol, the combination has not been shown to provide any additional benefit.

Remifentanil is an ester derivative of fentanyl and also has ultra—short-acting sedative and analgesic properties. Traditionally used in general anesthesia for sedation and analgesia, it has been described in brief reports for ED PSA. It has the unique advantage of being metabolized by esterases present in interstitial tissues and red blood cells, and therefore its metabolism is independent of hepatic or renal dysfunction. It can have significant respiratory depression, but the patient is still often responsive to verbal commands.

Dexmedetomidine is a newer sedative agent for use in the ED. To date, literature supporting its use in the ED has been limited to a few case reports in the PSA population in the ED. It acts as a highly selective α₂-adrenergic agonist with sedative, anxiolytic, and analgesic properties. Dexmedetomidine induces natural sleep to create its sedative effects. It has been mainly administered via infusion and has been used safely and successfully to facilitate fiberoptic intubation, gastrointestinal (GI) procedures and cardioversions. More intensive care unit (ICU) reports have demonstrated its use as a preferred sedative agent for mechanically ventilated patients. It may be considered for use with sedation of patients who are insensitive to the usual doses of benzodiazepines.

**Reversal and Rescue Agents.** Careful titration of medications to the desired level of sedation is generally the goal in PSA. At times, however, unanticipated deeper levels of sedation may be reached, and respiratory depression or apnea may be experienced. Airway repositioning, supplemental oxygen, and bag-valve-mask ventilation may be required. If these periods are prolonged, partial or complete reversal of agents such as opioids or benzodiazepines may be necessary. Elective reversal of PSA after completion of the procedure is not recommended.

**Naloxone.** Naloxone is a competitive antagonist of opioids and has been effectively used for the reversal of opioid-induced respiratory depression during PSA. It has a rapid onset of action and a mean plasma half-life of approximately 45 minutes, although its clinical effects last only 15 to 30 minutes. Resedation is generally not a problem for patients who have been given short-acting opioids such as fentanyl or morphine in doses recommended for PSA. Nevertheless, these patients should be observed for a minimum of 1 hour after the administration of naloxone. It is especially important for patients who have received large doses of fentanyl to ensure that redistribution of fentanyl within the body does not result in the recurrence of sedation.

Naloxone may be administered via the IV, IM, subcutaneous, or endotracheal route, but it is almost universally given IV. The smallest dose necessary to restore respiratory effort should be used because reversal of the opioid's respiratory depressant effect is matched by reversal of the analgesia. The initial dosage depends on the patient and the specific goals desired. For partial reversal, titrated doses of 0.1 to 0.2 mg may be used every 1 to 2 minutes to desired effect. Complete reversal is almost never desirable and requires doses of 1 to 2 mg. Similar doses may be used for children. In patients who are opioid-dependent, these doses may precipitate an acute withdrawal state. Smaller initial doses should be considered. Large doses of naloxone may also make it more difficult to control postprocedural pain. Naloxone use has little risk, but pulmonary edema, seizure, and dysrhythmia rarely have been reported.

**Flumazenil.** Flumazenil is a competitive antagonist of benzodiazepines. Although it reverses the sedation effect of benzodiazepines, it is not as effective for reversing respiratory depression. In general, when oversedation occurs, brief support of ventilation permits the patient to recover sufficient spontaneous respiration without the need for reversal. Flumazenil has a rapid onset of action in 1 to 2 minutes, peak effect in 5 to 10 minutes, and individually variable clinical duration of 30 to 90 minutes. Continuous patient monitoring must be ensured when flumazenil is used to reverse respiratory depression associated with longer lasting benzodiazepines because resedation is likely. Flumazenil has also been shown to be effective in reversing paradoxical excitement in children.

It is generally titrated in doses of 0.1 to 0.2 mg IV every 1 to 2 minutes to the desired effect. A maximum dose of 1 mg is generally sufficient. Common pediatric doses of 0.02 mg/kg are generally used, with a maximum of 0.2 mg. It should be used with extreme caution in patients with benzodiazepine dependence or a history of seizures because it may precipitate life-threatening status epilepticus refractory to common treatment. Routine reversal is not recommended.

CHAPTER 4  Procedural Sedation and Analgesia

For brief nonpainful procedures requiring complete immobilization, IV midazolam and propofol are excellent choices, and etomidate is a reasonable alternative. For longer procedures, oral or rectal midazolam or propofol infusion is reasonable.

For briefly painful procedures requiring minimal to moderate sedation, and when topical or local anesthetics may be used (eg, for reduction of a glenohumeral dislocation for which intraarticular lidocaine will be used), midazolam is a reliable and safe choice. IV propofol, preceded by a modest dose of fentanyl, is an excellent choice for brief painful procedures requiring deep sedation (eg, cardioversion, joint reduction, other highly painful procedures). Ketamine by the IV and IM routes has been extensively studied in children and is highly effective, with a large margin of safety for children and adults. The same may be said for IV midazolam plus fentanyl in the adult and pediatric populations.

Drug Selection and Administration

When choosing a strategy for PSA, it is important to consider the type of procedure being performed (painful or not), length of the procedure, specific procedural requirements (anxiolysis vs. immobility), and whether sedation may need to be prolonged (Table 4.5). The need for IV access generally is an issue only in small children. Planned adjuncts, such as topical, local, or regional anesthesia, are also considered. Patient factors, including age, medications, alcohol and drug use, and comorbid conditions, are considered when selecting the agent and initial dose. Procedures necessitating sedation may be broadly divided into three categories—nonpainful procedures requiring immobilization (eg, CT, MRI); low-pain, high-anxiety procedures (eg, laceration repair, lumbar puncture); and highly painful, high-anxiety procedures (eg, fracture or joint reduction, tube thoracostomy, abscess drainage, cardioversion).

For brief nonpainful procedures requiring complete immobilization, IV midazolam and propofol are excellent choices, and etomidate is a reasonable alternative. For longer procedures, oral or rectal midazolam or propofol infusion is reasonable.

For briefly painful procedures requiring minimal to moderate sedation, and when topical or local anesthetics may be used (eg, for reduction of a glenohumeral dislocation for which intraarticular lidocaine will be used), midazolam is a reliable and safe choice. IV propofol, preceded by a modest dose of fentanyl, is an excellent choice for brief painful procedures requiring deep sedation (eg, cardioversion, joint reduction, other highly painful procedures). Ketamine by the IV and IM routes has been extensively studied in children and is highly effective, with a large margin of safety for children and adults. The same may be said for IV midazolam plus fentanyl in the adult and pediatric populations.
CHAPTER 4: QUESTIONS & ANSWERS

4.1. When do most adverse events associated with emergency department procedural sedation occur?
   A. During the manipulation or intervention
   B. 5 to 20 minutes after the last sedative dose
   C. 20 to 30 minutes after the last sedative dose
   D. 30 to 60 minutes after the last sedative dose
   E. 60 to 90 minutes after the last sedative dose

Answer: B. High-risk times are 5 to 20 minutes after the last medication administration and at the completion of the procedure, when there is no longer a painful stimulus but the patient remains sedated.

4.2. Which of the following modalities has proven most effective for monitoring patients undergoing procedural sedation?
   A. Capnometry or capnography
   B. Cardiac rhythm monitoring
   C. Continual direct visual observation of qualitative clinical signs
   D. Documented respiratory rate
   E. Pulse oximetry

Answer: C. The patient’s ability to follow commands in response to varied levels of stimulation and direct observation of the ventilatory status have been the most reliably documented methods of assessing the level of consciousness during procedural sedation. Pulse oximetry is a reliable adjunct, but it identifies hyperventilation late, especially when used with supplemental oxygen. Cardiac monitoring has been shown to be helpful in older patients or in those with a history of cardiac disease, but there is no evidence that it is of any benefit in young healthy patients. End-tidal carbon dioxide (CO2) monitoring has been shown to be useful to detect inadequate ventilation earlier than oximetry, especially when direct observation of the patient is difficult, but no studies have demonstrated an effect on clinical outcome to date. The American Society of Anesthesiologists (ASA) has updated its procedural sedation standards to include capnography during moderate or deep sedation, in addition to the continual observation of qualitative clinical signs. Respiratory rate alone is an insensitive indicator of the adequacy of ventilation.

4.3. Which of the following statements is most accurate regarding the use of fentanyl for procedural sedation?
   A. Fentanyl is a long-acting analgesic.
   B. For deep sedation, a single dose of 1 to 2 µg/kg IV is often given before sedation to achieve good pain control. A smaller dose of sedative agent may then be added and titrated to effect.
   C. Rapid IV administration is generally safe.
   D. Respiratory depression is less likely with fentanyl than with equipotent dose of morphine.
   E. Sufficient analgesia is generally attained with dosages of 5 to 10 µg/kg intravenous (IV).

Answer: B. For deep sedation, less respiratory depression is generally observed if a single pain-relieving dose of fentanyl is used before sedation, followed by small titrated doses of a sedative agent. Sufficient analgesia is generally attained with fentanyl dosages of 1 to 2 µg/kg IV. Rapid IV administration of large doses is more likely to precipitate respiratory depression or arrest. Chest wall rigidity is very rarely seen and generally only with large, rapid, IV boluses of more than 7 µg/kg IV. If severe chest wall rigidity syndrome is precipitated, it often requires paralysis to ventilate the patient adequately. It is not reversed with naloxone. Equivalent dosages of morphine show more histamine release and hypotension than fentanyl but have similar respiratory depression potential.

4.4. Which of the following agents is matched with the correct associated side effect?
   A. Etomidate—limited (30-minute) duration of sedation
   B. Ketamine—laryngospasm
   C. Methohexital—venoeritration
   D. Pentobarbital—seizures
   E. Propofol—myoclonus

Answer: B. Ketamine has been associated with laryngospasm in children younger than 3 months and those with a respiratory infection. The following are the other correct associations:
   - Methohexital—seizures
   - Propofol—venoeritration
   - Pentobarbital—30-minute duration
   - Etomidate—myoclonus

4.5. Which of the following statements regarding the use of ketamine is false?
   A. Benzodiazepine coadministration has not been shown to reduce the incidence of emergence phenomenon in children.
   B. Despite increased secretions, airway reflexes are generally well maintained.
   C. Hypotension is common.
   D. Profound analgesic and sedative effects occur with minimal respiratory depression.
   E. Repeat doses are well tolerated in longer procedures.

Answer: C. Ketamine increases the release of catecholamines on administration and supports blood pressure well. It also decreases smooth muscle tone in the bronchial tree and may have a benefit in patients with reactive airways disease. Several studies have failed to show benefit with the concurrent administration of low to moderate dosages of benzodiazepines in preventing emergence phenomenon in children. These studies have shown a slightly increased risk of side effects. Their routine use is discouraged and should be reserved for the actual treatment of severe emergency phenomenon.

4.6. Which of the following statements regarding the use of propofol is true?
   A. Propofol has a long duration of action and provides significant analgesia.
   B. Propofol has significant antiemetic properties.
   C. Propofol is cerebroprotective.
   D. Propofol is well tolerated in volume-depleted patients.
   E. The use of ketofol (ketamine in combination with propofol) is clinically superior to the use of propofol alone.

Answer: B. Propofol is an ultra–short-acting, sedative-hypnotic, cerebroprotective agent with no analgesic but profound antiemetic properties. Its adverse effects include dose-dependent respiratory depression, apnea, hypotension, and pain on injection. Preload-dependent patients are particularly susceptible to hypotension. Its combined use with ketamine is common. The two agents are thought to have synergistic effects that balance each other’s deficits. Their combined use has been shown to improve provider satisfaction, sedation quality, and decrease emesis but has not been shown to be clinically superior to either agent used alone in regard to respiratory depression, airway complications, or improved recovery times.
4.7. Which of the following statements is true regarding the need for fasting before procedural sedation?

A. A 6-hour period of fasting is required after the ingestion of liquids or solids before procedural sedation.
B. Preprocedural fasting is required in all cases.
C. The recommendation for preprocedural fasting is based on controlled trials involving patients undergoing procedural sedation.
D. The risk of vomiting and loss of the airway protective reflexes is an extremely rare occurrence during procedural sedation.
E. There is an increased risk of aspiration during procedural sedation after a liquid or solid meal.

Answer: D. The ASA currently recommends a period of 2 hours after ingestion of clear liquids, 4 hours after ingestion of breast milk, and 6 hours after the ingestion of other liquids or solids before the performance of procedural sedation. This recommendation is based on expert consensus and has been extrapolated from data on patients receiving general anesthesia and manipulation of the airway during intubation and extubation. There are no published studies showing an increased risk of aspiration after a liquid or solid meal nor benefits of fasting before procedural sedation. Large studies have shown no clinically significant differences with airway complications, emesis, or other adverse effects among groups of patients stratified by their preprocedural fasting status. The risks of procedural sedation should be balanced against the risks of delaying a time-sensitive procedure.
CHAPTER 5

Monitoring the Emergency Patient

Anthony M. Napoli | Ken Deitch

This chapter focuses on these monitoring modalities: noninvasive blood pressure measurement, pulse oximetry, and use of the end-tidal carbon dioxide (ETCO₂) measurement. Fetal monitoring after trauma and cerebral function monitoring are also briefly discussed.

BLOOD PRESSURE MEASUREMENT

Principles

Blood pressure measurement by sphygmomanometry is the most common method of noninvasively measuring arterial pressure by indirectly measuring systolic, diastolic, mean arterial, and pulse pressures. The pulse pressure is important because it closely resembles stroke volume when accounting for arterial compliance and resistance. At a given arterial compliance (C), stroke volume (SV) is associated with corresponding changes in pulse pressure: C = SV/PP. Therefore, blood pressure closely represents the interplay of cardiac output and overall systemic vascular resistance, making it an important screening and surrogate monitoring tool in emergency department (ED) patients.

Decision Making

Blood pressure monitoring remains a standard and important ongoing measure of changes in the physiologic adaptation to stress and serves as a dynamic measure and singular predictor of adverse outcomes in medical and surgical patients. For example, patients who present to the ED with sepsis are six times more likely to progress to septic shock if they have even a single episode of hypotension. Similar results have been shown in trauma patients, for whom apparently isolated hypotension is associated with increased mortality.

Devices and Techniques

Traditional blood pressure measurement by sphygmomanometry can be obtained by Doppler, palpation, auscultation, and oscillometric methods. Although palpation only allows for systolic pressure determination, it is useful in noisy environments (such as emergency medical services [EMS] transport), where measurement by oscillometric means may be difficult. Doppler is particularly helpful in identifying the presence of a systolic pulse in hypotensive patients or in internally (ie, atherosclerosis) or externally (ie, compartment syndrome) flow-limited extremities. Auscultation, otherwise known as manual blood pressure measurement, has remained a common, generally reliable, and reproducible method of blood pressure measurement for over 100 years, since its discovery. This method relies on placing the stethoscope at the antecubital fossa, inflating the blood pressure cuff, and then slowly deflating the cuff while noting the pressure at which auscultation of the pulse returns (systolic blood pressure) and when it disappears (diastolic blood pressure). Auscultation generally underestimates the systolic blood pressure and overestimates the diastolic pressure. Although accuracy has improved with standardization of the technology, this technique is occasionally prone to significant inaccuracy. The quality of the device, cuff size, body positioning, arm positioning, and relaxation are all components of the measuring technique that can affect the accuracy. Clinical circumstances such as obesity, dysrhythmias, and extremes of age (young children and older adults) may also affect the accuracy.

The ease of use of oscillometric blood pressure measurement makes this modality ideal for ED noninvasive monitoring. The oscillometric technique measures oscillations in the pressure during deflation of the cuff; the maximal point of oscillation represents the mean arterial pressure. This is the most common noninvasive method of measuring blood pressure in the ED and is commonly called the automatic blood pressure. This method has several advantages over auscultation, including less susceptibility to noise, less resource usage, and regular measurement intervals, and specific placement of a transducer over the artery is unnecessary. Comparisons of auscultation and oscillometric measurement with intraarterial measurement have found relatively good agreement, with automated pressures slightly overestimating manual systolic pressures with moderate precision in hemodynamically stable patients.

Other methods of providing continuous, noninvasive blood pressure monitoring often rely on partial radial artery compression or arterial loading counterpressure and offer results comparable to those of an arterial catheter, with the benefit of added mobility. Newer continuous, noninvasive blood pressure monitors have the advantage of providing additional advanced hemodynamic measures, such as stroke volume and cardiac output, which may be beneficial in critically ill patients.

The gold standard, and the most accurate method of measuring blood pressure, remains the intraarterial catheter. However, this method is invasive and time intensive, and carries the infrequent but real risk of arterial injury or thrombosis. Common situations in which invasive arterial monitoring may be of benefit include (1) persistent or recurrent hemodynamic instability, (2) monitoring of conditions or treatments that result in large fluid or blood pressure shifts, (3) frequent arterial blood sampling, and (4) expected inaccuracies in noninvasive blood pressure management (eg, because of obesity or dysrhythmias).

PULSE OXIMETRY

Principles

Pulse oximetry is widely used for ED and out-of-hospital patient monitoring. It provides a real-time assessment of oxygen saturation and objective insight into dynamic changes in patient physiology, as well as the effectiveness of interventions as related to oxygenation. Since widespread adoption nearly 35 years ago, it is now become regarded as the fifth vital sign.

Decision Making

ED use of pulse oximetry was adapted from anesthesiology practice, which demonstrated less frequent and shorter episodes of desaturation and earlier recognition of hypoxia during or after
anesthesia. In the ED, pulse oximetry is largely used for the initial triage of patients or in the monitoring and management of patients who are sedated or critically ill, particularly with respiratory distress or during endotracheal intubation. In the latter case, pulse oximetry has been shown to reduce the frequency of hypoxic episodes. Arterial oxygen saturation (SaO2) values at or below 96% have been shown to be 100% sensitive for the detection of hypoxia (partial pressure of arterial oxygen [PaO2] < 70 torr), although such a cutoff can be different in patients with obstructive lung disease.

**Devices and Techniques**

Pulse oximetry is based on the premise that the concentration of an absorbing substance can be determined if the characteristic wavelength of that substance, intensity of the light transmitted through the substance, and distance of transmission are known (Beer-Lambert Law). Pulse oximetry devices use two light-emitting diodes (LEDs) that give off light at wavelengths characteristic of oxyhemoglobin and deoxyhemoglobin (660 and 940 nm). These wavelengths are absorbed at different rates depending on clinical conditions, and the fractional difference between the two wavelengths is measured and reflected in the pulse oximetry. Because the absorption characteristics of tissue, arterial blood, and venous blood are static over a cardiac cycle, the beat to beat alterations that occur in pulsatile blood can be isolated, and the static components can be filtered out through measurement of transmitted light several hundred times per second. Measurements can be made on the ears or fingers, although the fingers are generally better in patients with poor perfusion.

Pulse oximetry measures the percentage of arterial hemoglobin that is in the oxyhemoglobin state. It reflects the amount of oxygen that hemoglobin is carrying as a percent of the maximum it can carry; this is commonly known as the oxygen saturation as measured by pulse oximetry (SpO2). Pulse oximetry does not measure the PaO2; however, hemoglobin-bound oxygen represents the larger reservoir of oxygen in the blood. An understanding of the oxyhemoglobin dissociation curve and relationship between SaO2 and PaO2 makes it possible to advance monitoring capacity using this noninvasive continuous monitor to replace intermittent arterial blood draws. Although the two measures correlate well, their relationship is nonlinear. Pulse oximeters are generally accurate between 80% and 100% saturation, but large changes in the SpO2 can occur with small changes in the PaO2 in hypoxic patients. Below this range, the role is reversed, and large changes in PaO2 may occur with small changes in SpO2. Pulse oximetry retains its usefulness because in the no-hypoxic range, the relationship generally is linear and, once clinically important hypoxia exists, there is no significantly different clinical response to a pulse oximeter reading of 85% or 65%. In this way, pulse oximetry is an ideal tool for screening and continuous monitoring.

Pulse oximetry has several important clinical limitations. By design, pulse oximeters measure only two wavelengths. At these wavelengths, traditional pulse oximeters are unable to distinguish oxyhemoglobin and deoxyhemoglobin from two important dys-hemoglobinemas, methemoglobin (MetHb) and carboxyhemoglobin (COHb). Multispectral CO2 oximeters are now available that can distinguish the four wavelengths. In the setting of a significant MetHb or COHb exposure, the pulse oximeter will read falsely elevated levels of SaO2, even at relatively high exposures, because it cannot distinguish oxygenated or deoxygenated hemoglobin from these other dys-hemoglobinemas. In heavy smokers, COHb levels of 3% to 15% can commonly be found, but this has little impact on the reported SpO2. Signal artifact is probably the most common technical limitation to adequate measurement. Other limitations include low perfusion states, which lead to a low pulsatile component and subsequent impaired measurement accuracy, ambient light, deep skin pigmentation, methylene blue, and nail polish. Signal averaging limits the impact of motion artifact and improves its accuracy.

Determination of the SpO2 may obviate the need for repeated, invasive arterial sampling to determine oxygen saturation (and to some degree PaO2), but it does not adequately provide insight into the pH or partial pressure of carbon dioxide (Paco2). These latter two data points can be obtained by venous blood sampling and use of continuous capnography. More importantly, SpO2 does not aid in determining the adequacy of ventilation when significant hypercapnia may precede hypoxia, and supplemental oxygen may mask hypoventilation. This is one of the many uses of ETco2 measurement.

**END-TIDAL CARBON DIOXIDE MONITORING**

**Principles**

Capnography is the graphic record, represented as a waveform, or capnogram, of the instantaneous CO2 concentrations in respired gases during a respiratory cycle. Near-instantaneous measurement of the pattern of each breath and concentration of exhaled carbon dioxide allows the emergency clinician to determine the baseline ventilatory status and track changes over time. Capnometry is defined as the quantitative measurement of ETco2, displayed as a number without a waveform. Colorimetric detectors use color scales to estimate ranges of ETco2 but are not sufficiently accurate to give precise quantitative measurements. Their use is therefore limited to confirmation of correct endotracheal tube (ETT) placement and its continuous location in the trachea. Capnography has broad application in the ED during procedural sedation and monitoring of critically ill or intubated patients, and also is used in the out-of-hospital setting to monitor intubated and sedated patients.

ETco2 monitors are configured as sidestream or mainstream, depending on the location of the photoelectric detector or sensor. Mainstream devices measure CO2 directly from the airway, with the sensor attached directly to the ETT. Sidestream devices, more commonly used by EMS personnel and in the ED, aspirate a sample of gas through tubing into a sensor located inside the monitor and are used for intubated and nonintubated patients. They are lightweight and may be integrated into a nasal-oral cannula that simultaneously samples CO2 and delivers low-flow oxygen, allowing for continuous oxygen delivery during procedural sedation and analgesia.

Colorimetric CO2 detectors use pH-sensitive filter paper impregnated with metacresol purple, which changes color from purple (<4 mm Hg CO2) to tan (4–15 mm Hg CO2) to yellow (>20 mm Hg CO2), depending on the concentration of CO2 (see Chapter 1). The indicator, housed in a plastic casing, is inserted between the ETT and ventilator bag and detects changes on a breath by breath basis.

**Anatomy and Pathophysiology**

Although the concentrations of CO2 can be displayed continuously throughout the respiratory cycle—by convention only the maximum CO2 concentration at the end of each tidal breath—the ETco2, is ordinarily displayed. In patients with normal cardiopulmonary function, there is a close correlation between the alveolar CO2 (Paco2) and arterial CO2 (Paco2). The ETco2 is usually 2 to 5 mm Hg less than the Paco2 because of the dilution of the endtidal gases by physiologic dead space gas. Conditions that affect ventilation-perfusion ratios (including pulmonary embolism), cardiac arrest, hypovolemia, obstructive lung disease, and lateral decubitus position can widen the Pa–ETco2 gradient. Several studies, however, have shown high concordance between ETco2
and \( \text{PacO}_2 \) in adult asthmatics and in children with moderate and severe respiratory distress from bronchiolitis, asthma, and pneumonia. Analysis of the shape of the capnogram can yield valuable diagnostic information.

A normal capnogram has four phases (Fig. 5.1A):

1. Phase 1-2 represents a \( \text{CO}_2 \)-free portion of the respiratory cycle. Usually, this is the inspiratory phase, although it may represent apnea or a disconnection of the device from the patient. An elevation of this baseline above zero implies rebreathing of \( \text{CO}_2 \), as in increased dead space in the circuit or contamination of the sensor.

2. Phase 2-3, the rapid upstroke of the curve, represents the transition from inspiration to expiration and the mixing of dead space and alveolar gas. Prolongation of phase 2-3 (see Fig. 5.1B) occurs with obstruction to expiratory gas flow (eg, obstructive lung disease, bronchospasm, kinked ET) or leaks in the breathing system.

3. Phase 3-4, the alveolar plateau, represents the predominance of \( \text{CO}_2 \)-rich alveolar gas in the breath stream and tends to slope gently upward with the uneven emptying of alveoli. Point 4 (the \( \text{ETCO}_2 \)) represents the maximum \( \text{CO}_2 \) concentration in each breath and is the number that appears on the monitor. The slope of this phase can be increased by the same obstructive factors that increase the slope of phase 2-3 and is also a normal physiologic variation in pregnancy. A dip in the plateau indicates a spontaneous respiratory effort during mechanical ventilation, as in hypoxia, hypercarbia, or inadequate anesthesia (see Fig. 5.1C).

4. Phase 4-5, the inspiratory downstroke, is a nearly vertical drop to baseline. This slope can be prolonged and blend in with the expiratory phase in endotracheal cuff leaks (see Fig. 5.1D). Abnormal respiratory patterns that are fast or chaotic limit the usefulness of \( \text{ETCO}_2 \) monitoring because characteristic waveform patterns are difficult to discern.

Management

Capnography is used in the ED for intubated and nonintubated patients. For intubated patients, it provides information regarding respiratory function and ventilator settings and gives immediate notification of accidental extubation. Postintubation, an \( \text{ETCO}_2 \) waveform demonstrating all four phases indicates that the endotracheal tube is through the vocal cords and is not obstructed. In patients who are not in cardiac arrest, qualitative colorimetric \( \text{ETCO}_2 \) or quantitative capnography provides nearly 100% sensitivity and specificity for endotracheal placement. In contrast, using clinical signs to verify endotracheal tube placement is unreliable, with a high rate of false-positive results. \( \text{ETCO}_2 \) can help monitor tube position continuously in the trachea during transport and is an accepted standard of care by the American Society of Anesthesiology and other organizations. During cardiac arrest, \( \text{ETCO}_2 \) reflects the degree of pulmonary blood flow as alveolar ventilation and basal metabolism are constant, so that it can be used to gauge effectiveness of cardiopulmonary resuscitation (CPR) and return of spontaneous circulation (see Chapter 8).

In addition to uses in resuscitation, capnography can also be used to monitor patients with active seizures and maintain appropriate \( \text{ETCO}_2 \) levels in patients with elevated intracranial pressure. Along with visualizing tracheal rings on bronchoscopy, capnography is the other gold standard used to confirm intubation of the trachea (see Chapter 1).

Capnography in Spontaneously Breathing Patients

Rapid Assessment of Critically Ill Patients. Airway, breathing, and circulatory assessment of critically ill patients can be rapidly determined through the use of \( \text{ETCO}_2 \) values and the capnogram. The presence of a normal capnogram denotes a patent airway and spontaneous breathing, and normal \( \text{ETCO}_2 \) levels indicate adequate ventilation and perfusion. Unlike pulse oximetry and electrocardiography, capnographic measurement is airway based and therefore is not subject to motion artifact. It also provides reliable readings in low-perfusion states. Capnography is the only ventilation monitoring modality that is accurate and reliable in patients with active generalized seizures. Capnographic data (capnogram, \( \text{ETCO}_2 \), respiratory rate) can be used to distinguish among actively seizing patients with apnea (flatline waveform, no \( \text{ETCO}_2 \) readings, no chest wall movement), ineffective
ventilation with low–tidal volume breathing (small capnograms, low ET\textsubscript{CO}_2), and effective ventilation (normal capnogram, normal ET\textsubscript{CO}_2).

Capnography can also rapidly detect the common airway, respiratory, and central nervous system complications associated with nerve agents used in chemical terrorism, including apnea, upper airway obstruction, laryngospasm, bronchospasm, and respiratory failure.\textsuperscript{2}

Assessment and Measurement of Response to Treatment in Patients With Acute Respiratory Distress. Capnography provides dynamic monitoring of ventilatory status in patients with acute respiratory distress, such as from asthma, bronchiolitis, chronic obstructive pulmonary disease (COPD), congestive heart failure, and cystic fibrosis. By measuring ET\textsubscript{CO}_2 and respiratory rate with each breath, capnography provides instantaneous feedback on the clinical status of the patient. Respiratory rate is measured directly from the airway via a nasal-oral cannula, providing a more reliable reading than impedance respiratory monitoring. In upper airway obstruction and laryngospasm, for example, impedance monitoring detects chest wall movement, interprets this as a valid breath, and displays a respiratory rate, even though the patient is not ventilating. In contrast, capnography detects no ventilation and shows a flatline capnogram.

Bronchospasm in obstructive lung disease leads to upward slanting of the expiratory plateau of the capnogram (Fig. 5.2, middle panel). Changes in ET\textsubscript{CO}_2 over time and the slope of this phase of the capnogram have been shown to correlate well with spirometric measurements (forced expiratory volume in 1 second [FEV\textsubscript{1}] and peak expiratory flow rate [PEFR]). Capnography has the advantage of being independent of effort, gender, age, and height and is a useful objective measure in asthmatic patients who are unable to cooperate with spirometry (eg, young children, ventilated patients, patients in acute respiratory distress). Capnography can also be used to distinguish obstructive from restrictive lung disease. Characteristic capnographic patterns associated with restrictive and obstructive lung disease are shown in Fig. 5.2 (bottom panel). A recent pilot study has shown early promise in a computerized algorithmic approach for the classification of waveforms differentiating congestive heart failure and COPD with a high degree of sensitivity and specificity.\textsuperscript{7}

During Procedural Sedation and Analgesia. Capnography can also detect the common adverse airway and respiratory events associated with procedural sedation and analgesia (see Chapter 4). Central and obstructive apnea can be almost instantaneously detected by capnography. Capnography is the earliest indicator of airway or respiratory compromise and displays an abnormally high or low ET\textsubscript{CO}_2 5 to 240 seconds before pulse oximetry detects a falling oxyhemoglobin saturation, especially in patients receiving supplemental oxygen. A low ET\textsubscript{CO}_2—that is, hypopneic hypventilation—is commonly seen with sedative-hypnotic agents (especially propofol) and during deep sedation, represents low–tidal volume breathing (airway dead space remains constant but tidal volume decreases), and should not be misinterpreted as hyperventilation.

The use of capnography during procedural sedation in adults and children is associated with significantly lower rates of hypoxia. Early recognition of respiratory depression allows for earlier airway interventions and results in lower rates of hypoxia in patients undergoing procedural sedation (see Chapter 4).

**Rapid Assessment of Obtunded or Unconscious Patients.** Obtunded or unconscious patients, with or without psychomotor agitation, includes those with alcohol intoxication, intentional or unintentional drug overdose, postictal patients, and agitated patients treated with benzodiazepines, who may have respiratory depression, impaired ventilation, and hypoxia. Capnography may differentiate between postictal patients with effective ventilation and those with ineffective ventilation, as well as providing continuous monitoring of ventilatory trends over time to identify patients at risk for respiratory depression and respiratory failure.\textsuperscript{8,9}

**Rapid Assessment of Patients With Severe Illness.** This includes those with sepsis, diabetic ketoacidosis, and dehydration. In addition to its established uses for assessment of ventilation and perfusion, capnography is a valuable tool for evaluating metabolic status. Studies have shown a positive linear correlation between ET\textsubscript{CO}_2 and serum bicarbonate ion (HCO\textsubscript{3}\textsuperscript{−}) levels in those with diabetes and gastroenteritis; ET\textsubscript{CO}_2 can be used as an indicator of metabolic acidosis in these patients (Figs. 5.3 and 5.4). As a patient becomes acidotic, the HCO\textsubscript{3}\textsuperscript{−} level decreases and a compensatory respiratory alkalosis develops, with an increase in minute ventilation and a resultant decrease in ET\textsubscript{CO}_2. The more acidic the patient, the lower the HCO\textsubscript{3}\textsuperscript{−}; the higher the respiratory rate, the lower the ET\textsubscript{CO}_2. Furthermore, ET\textsubscript{CO}_2 can be used to distinguish diabetics with ketoacidosis (metabolic acidosis, compensatory tachypnea, low ET\textsubscript{CO}_2) from those without (nonacidotic, normal respiratory rate, normal ET\textsubscript{CO}_2). A similar association between ET\textsubscript{CO}_2 and HCO\textsubscript{3}\textsuperscript{−} has been demonstrated in

![Fig. 5.2. Capnogram shape in normal subjects (top panel), patients with bronchospasm (middle panel), and those with obstructive and restrictive (bottom panel) lung disease. FEV\textsubscript{1}, Forced expiratory volume in 1 second; FVC, forced vital capacity.](image)

Cerebral Function Monitoring

**Principles**

The bispectral index (BIS) is used to monitor, analyze, and process a patient’s electroencephalogram during sedation to produce a single number, the BIS score. This unitless number, values from 0 to 100, is used as an indicator of the depth of sedation, with 0 representing electroencephalographic silence and 100 a fully awake adult.

BIS monitoring has been studied in the ED in an attempt to objectify sedation endpoints by titrating to a target BIS score. However, the evidence of its ability to reflect depth of sedation reliably is conflicting. More importantly, the threshold beyond which ventilatory compromise occurs has not been determined, further limiting the usefulness of routine BIS monitoring for sedation in the ED. BIS monitoring reliably distinguishes patients undergoing procedural sedation and analgesia who were sedated to the point of general anesthesia from those with lesser degrees of sedation, but does not discriminate mild to moderate sedation from moderate to deep sedation. The use of BIS monitoring during procedural sedation is discussed in Chapter 4.

Another technology that monitors cerebral function is cerebral oximetry. Cerebral tissue oxygenation (ie, regional oxygen saturation [rSO2]) is measured by near-infrared spectroscopy monitoring of the nonpulsatile signal component, reflecting tissue circulation of the cerebral vasculature. This technology has been primarily studied in the operating room. It does not work as an early warning device, and its use in the ED is limited.

**FETAL MONITORING**

**Principles**

A small but significant percentage of all pregnancies (6%–7%) are complicated by traumatic and/or accidental injury. Trauma represents the leading nonobstetric cause of death and carries a mortality rate of 6% to 7%. Most traumatic injuries are motor vehicle accidents, but assaults, domestic abuse, and falls are also common. Uterine contractions occur in almost 50% of patients, although preterm labor and preterm delivery are much less common—5% to 15% and 1% to 2% of the time, respectively. However, peripartum complications and early preterm birth are difficult to predict after trauma. As a result, the Eastern Association for the Surgery of Trauma recommendations include cardiotocographic monitoring for a minimum of 6 hours after trauma in women at more than 20 weeks’ gestation. In addition to serial examination, fetal monitoring allows for the identification of uterine contractions and nonreassuring heart rate changes.

Although the optimal period of monitoring has not been determined, further monitoring is recommended when abnormalities are identified or serial examination findings warrant it. Emergency clinicians generally do not monitor for cardiotocographic findings and, as a result, term or near-term pregnancies are generally transferred for such monitoring. ED bedside ultrasonography is available more commonly and can demonstrate fetal heart rate and movement. However, ultrasonography requires intermittent examinations, has limited ability to track fetal heart tones, and is unable to measure uterine contractions. Ongoing fetal monitoring in a third-trimester pregnancy after trauma is typically accomplished by admission or observation by the obstetric service.

**Monitor Alarms and Limits**

Continuous vital sign monitoring, with alarm thresholds that notify staff regarding changes in physiologic conditions, has become a routine part of ED care. Although these alarms are designed to be highly sensitive, their lack of specificity has the potential to desensitize staff and reduce alarm effectiveness in identifying important changes in the clinical condition (ie, nuisance alarms). Continuous monitoring in select patient populations, such as those with low-risk chest pain, has limited usefulness, with less than 1% of alarms resulting in a change in clinical management. A multidisciplinary team-based approach that focuses on identifying optimal application of monitoring, standardizing alarm limits and the staff response, and using improved alarm technology has the potential to improve patient safety and enhance workplace efficiency and satisfaction.
Capnography supplements oximetry by providing useful information regarding pathologic conditions and response to therapy. It is highly correlated with cardiac output and therefore is a good indicator of the adequacy of cardiopulmonary resuscitation in arrest victims.

Capnography is also useful in spontaneously breathing patients. It can be a good indicator of perfusion, ventilatory response to therapy in respiratory distress patients, adequacy of ventilation during procedural sedation, and rapid assessment and response to therapy in patients with metabolic derangements.

Monitoring modalities, when used appropriately, help identify the effectiveness of interventions, predict deterioration, track the patient’s clinical course, and inform clinical decision making.

Noninvasive blood pressure monitors remain the standard for ongoing measurement of dynamic change. A single episode of hypotension is predictive of subsequent hemodynamic compromise. Despite generally high accuracy and dependability of blood pressure monitoring devices, determining blood pressure manually may be required at times to verify sudden changes in blood pressure measurements or when readings fluctuate rapidly, suggesting inaccuracy of the automated device.

Due to the nonlinear relationship of the oxyhemoglobin dissociation curve, pulse oximeters are helpful for screening and monitoring patients but are not an accurate measure of PaO2 in hypoxic patients and thus should be used with caution.

In the setting of MetHb or COHb exposure, the pulse oximeter reading may be falsely elevated; thus, a CO oximeter is necessary to distinguish oxygenated and deoxygenated blood from other dyshemoglobinemias.

CHAPTER 5: QUESTIONS & ANSWERS

5.1. A 27-year-old firefighter presents with a headache, chest pain, and severe shortness of breath after working at the scene of a house fire. The physical examination is remarkable for a blood pressure of 155/90 mm Hg, heart rate of 110 beats/min, respiratory rate of 28 breaths/min, oxygen (O2) saturation of 98% on room air, and clear lungs. The chest radiograph is unremarkable. Which of the following may be responsible for a normal O2 saturation despite such respiratory stress?

A. Carboxyhemoglobin
B. Cyanide
C. Melanin
D. Methemoglobin
E. Methylene blue

Answer: A. Pulse oximetry is based on differences in the optical transmission spectrum of oxygenated and deoxygenated hemoglobin. Pulse oximeters measure the pulse variation in red and infrared light transmitted through a tissue bed. Data averaged over several arterial pulse cycles are then presented as saturation. Carboxyhemoglobin (COHb) contributes to light absorption and causes errors in oximetry readings. The pulse oximeter senses COHb as though it were mostly oxyhemoglobin and provides a falsely high reading.

5.2. A 17-year-old male presents with fatigue, bluish-colored skin, and mild shortness of breath. He has recently been to the dentist to have his molars removed and reports that his only medications are ibuprofen and multiple applications of over-the-counter topical pain relief. The physical examination is remarkable for a blood pressure of 137/85 mm Hg, heart rate of 95 beats/min, respiratory rate of 20 breaths/min, and O2 saturation of 85% on room air. The chest radiograph is unremarkable. Which of the following is most likely responsible for this O2 saturation in the context of this presentation?

A. Carboxyhemoglobin
B. Cyanide
C. Lactate
D. Methemoglobin
E. Methylene blue

Answer: D. As with carboxyhemoglobin, methemoglobin (MetHb) contributes to pulse oximetry light absorption and causes an error in oximetry readings. MetHb produces a large pulsatile absorbance signal at red and infrared wavelengths. This forces the absorbance ratio toward unity, which corresponds to an oxygen saturation measured by pulse oximetry (SpO2) of 85%. Thus, with high levels of MetHb, the SpO2 is erroneously low when the arterial saturation is higher than 85% and erroneously high when the arterial saturation is less than 85%.

5.3. Which of the following conditions would lead to a prolongation of the rapid upstroke phase of the capnography curve?

A. Bronchospasm
B. Pneumothorax
C. Pregnancy
D. Pulmonary embolism
E. Sepsis

Answer: A. The rapid upstroke phase of the capnography curve represents the transition from inspiration to expiration and the mixing of dead space and alveolar gas. Prolongation of this phase occurs with obstruction to expiratory gas flow (eg, obstructive lung disease, bronchospasm, kinked endotracheal tube) or leaks in the breathing system.

5.4. Which of the following may lead to false-negative results when capnometry is used to confirm intubation of the trachea?

A. Bicarbonate infusion
B. Cardiac arrest
C. Chronic obstructive pulmonary disease
D. Pneumothorax
E. Pulmonary embolism

Answer: B. Capnometry can confirm intubation of the trachea but may give false-negative results in cardiac arrest if delivery of carbon dioxide (CO2) from the periphery to the lungs is sufficiently diminished. Misleading end-tidal CO2 (ETCO2) readings causing false-positive results can occur with esophageal intubation after bag-mask ventilation and ingestion of carbonated beverages or antacids. However, detection of ETCO2 usually ceases after six breaths and, if capnography is used, the tracings look abnormal. ETCO2 is also falsely elevated for 5 to 10 minutes after injection of sodium bicarbonate. In nonarrest settings, the ETCO2 approaches 100% sensitivity and specificity in confirming correct tube placement.
CHAPTER 6
Shock

Michael A. Puskarich | Alan E. Jones

PRINCIPLES

Background and Importance

In philosophic terms, shock can be viewed as a transition between life and death. Whether shock results from hemorrhage, sepsis, or cardiac failure, mortality rates exceed 20%. In scientific lexicon, shock results from the widespread failure of the circulatory system to oxygenate and nourish the body adequately. At the cellular level, shock alters mitochondrial energy transfer and evokes the production and accumulation of toxic chemicals. The emergency clinician identifies shock by linking the qualitative clinical impression, synthesized from the patient’s history of present illness, age, health status, and general appearance, to quantitative data, including vital signs, laboratory tests, urine output, and measurements of systemic oxygenation. When the clinical impression and quantitative data suggest widespread organ hypoperfusion, emergent resuscitation is used to restore tissue oxygenation and substrate delivery to prevent deterioration into a vicious cycle of systemic inflammation, organ dysfunction, and death. Anaphylaxis and its treatment are discussed in Chapter 109.

For years, shock has been classified into four broad categories based on Blalock’s 1934 description—hematologic, vasogenic, cardiogenic, and neurologic. This basic organization scheme remains useful today for discussions of pathophysiology. For discussions of management, a system based on the requisite treatment response is more clinically useful. Box 6.1 outlines five categories of shock that generally have specific mechanisms and treatments. The epidemiology of shock in the emergency department (ED) context is diverse and evolving. Traumatic, cardiogenic, or septic shock are diagnosed in fewer than 3% of ED patients. Our understanding of the metabolic, systemic, and inflammatory responses that occur in all types of circulatory shock and the specific pathophysiology of the major causes of shock has led to dramatic increases in the early identification and treatment of these states, with resultant improvement in outcomes.

Anatomy, Physiology, and Pathophysiology

At the subcellular level, shock first affects the mitochondria. Mitochondria function at the lowest oxygen tension in the body, but they consume almost all the oxygen used by the body. More than 95% of aerobic chemical energy comes from mitochondrial combustion of fuel substrates (fats, carbohydrates, ketones) plus oxygen into carbon dioxide (CO₂) and water. Mitochondria have therefore been referred to as the canaries in the coal mine because they consume almost all the oxygen used by the body. More than 95% of aerobic chemical energy comes from mitochondrial combustion of fuel substrates (fats, carbohydrates, ketones) plus oxygen into carbon dioxide (CO₂) and water. Mitochondria have therefore been referred to as the canaries in the coal mine because they are affected first in conditions of inadequate tissue perfusion. When mitochondria have inadequate oxygen, the cell catabolizes fuels to lactate, which accumulates and diffuses into the blood. In the setting of hypoxia, mitochondria are unable to provide sufficient energy to maintain cellular processes and, at a certain point, an irreversible series of intracellular cascades leads to cellular dysfunction, organ failure, and ultimately death.

Specific Causes

Hemorrhagic Shock

Hemorrhagic shock results from a rapid reduction in intravascular blood volume from any cause. Rapid hemorrhage generally causes an increase in the strength of cardiac contraction and heart rate (HR), followed by baroreceptor activation and peripheral vasoconstriction. Typically, an initial slight increase in the diastolic blood pressure (BP) with a narrowing of the pulse pressure progresses to a decrease in ventricular filling and cardiac output, causing a reduction in systolic BP. This response varies considerably with cardiopulmonary status, age, and presence of vasoactive medications. The responses of HR and BP are therefore notoriously variable in hemorrhage, so no firm conclusion can be made at the bedside about the presence, absence, or degree of hemorrhagic shock by simple evaluation of the HR and BP.

Even before the cardiac output begins to decline, blood flow is directed away from noncritical organs and tissues, and their cells produce and release lactic acid. Consequently, acidemia often precedes any significant decrease in cardiac output. However, the blood contains bicarbonate ions that buffer the blood pH, keeping it near neutral, even as lactic acid accumulates. The base deficit—amount of strong base that would have to be added to 1 L of blood to normalize the pH—represents an index of how far the bloodstream has dipped into this reserve. A normal base deficit is more positive than −2 mEq/L. The arterial and venous blood base deficit can become more negative early in hemorrhage, even while blood pH and BP remain normal. The base deficit, therefore, crudely represents the physiologic endpoint that distinguishes trivial blood loss from clinically significant hemorrhage. In addition to chemical buffering, the body responds to small reductions in arterial pH by activating brainstem chemoreceptors, which increase minute ventilation, leading to reduced partial pressure of carbon dioxide in the arterial blood (Paco₂), providing an additional means of compensating for evolving acidosis.

With progressive blood loss, cardiovascular reflexes can no longer sustain adequate filling of the vasculature, and frank hypotension supervenes. Arterial hypotension is generally and arbitrarily defined as an arterial BP less than 90 mm Hg. Usually coincident with the development of hypotension, the compensatory chemical and respiratory buffering mechanisms become overwhelmed, resulting in acidosis. The hypothalamic-pituitary-adrenomedullary axis is activated, releasing stress hormones and inducing glycojenolysis, lipolysis, and mild hypokalemia. Significant traumatic hemorrhage in otherwise normal ED patients, therefore, will generally cause an arterial lactate concentration greater than 4.0 mmol/L, Paco₂ less than 35 mm Hg, mild hyperglycemia (150–170 mg/dL) and mild hypokalemia (3.5–3.7 mEq/L). Although hemorrhagic hypotension reduces lung perfusion, arterial hypoxemia should not be attributed simply to blood loss, but instead should prompt investigation for aspiration, airway obstruction, alveolar consolidation, or lung injury.
However, gram-positive organisms are now the primary cause of sepsis in hospitalized patients, indicating that the pathophysiology of sepsis cannot be explained simply by the response to LPS. Septic shock often causes three major effects that must be addressed during resuscitation—hypovolemia, cardiovascular depression, and induction of systemic inflammation. Septic shock produces relative and absolute hypovolemia, reducing right ventricular filling. Absolute hypovolemia results from gastrointestinal volume loss, tachypnea, sweating, and decreased fluid intake during development of the illness. Further relative hypovolemia results from increased venous capacitance in conjunction with increased capillary leak and resultant loss of intravascular volume into third spaces. Septic shock causes direct myocardial depression. Measurements of cardiac contractility have shown that mechanical function becomes impaired early in the course of septic shock, even in the hyperdynamic stages. Circulating mediators, myocardial cellular injury from inflammation, and deranged metabolism interact synergistically to injure the heart during septic shock, and specific cytokines (most notably tumor necrosis factor alpha [TNF-α] and interleukin-1 beta [IL-1β]), overproduction of NO by inducible nitric oxide synthase (iNOS), and possibly impairment in mitochondrial oxidative phosphorylation, may all play a role. Similar to hemorrhagic shock, systemic inflammation causes capillary leak in the lung, resulting in ARDS. Widespread systemic inflammation likely plays a role in the development and persistence of multisystem organ failure in sepsis through microvascular and mitochondrial dysfunction. Clinical trials to date have yet to demonstrate the effectiveness of specific or general antiinflammatory therapies in mitigating this response, and the treatment of septic shock relies primarily on the reversal of shock, supportive care, and source control.

**Box 6.1**

Five Categories of Shock According to Primary Treatment of Causes and Problems

**Primarily Infusion of Volume**
- Hemorrhagic shock
- Traumatic
- Gastrointestinal
- Body cavity
- Hypovolemia
  - Gastrointestinal losses
  - Dehydration from insensible losses
  - Third-space sequestration from inflammation

**Volume Infusion and Vasopressor Support**
- Septic shock
- Anaphylactic shock
- Central neurogenic shock
- Drug overdose

**Improvement in Pump Function by Infusion of Inotropic Support or Reversal of the Cause of Pump Dysfunction**
- Myocardial ischemia
  - Coronary artery thrombosis
  - Arterial hypotension with hypoxemia
- Cardiomyopathy
  - Acute myocarditis
  - Chronic diseases of heart muscle (ischemic, diabetic, infiltrative, endocrinologic, congenital)
- Cardiac rhythm disturbances
  - Atrial fibrillation with rapid ventricular response
  - Ventricular tachycardia
  - Supraventricular tachycardia
- Septic shock with myocardial failure (hypodynamic shock)
- Overdose of negative inotropic drug
  - Beta blocker
- Calcium channel antagonist
- Structural cardiac damage
  - Traumatic (eg, flail mitral valve)
  - Ventriculoseptal rupture
  - Papillary muscle rupture

**Immediate Relief from Obstruction to Cardiac Output**
- Pulmonary embolism
- Cardiac tamponade
- Tension pneumothorax
- Valvular dysfunction
  - Acute thrombosis of prosthetic valve
  - Critical aortic stenosis
- Congenital heart defects in newborn (eg, closure of patent ductus arteriosus, with critical aortic coarctation)
- Critical idiopathic subaortic stenosis (hypertrophic obstructive cardiomyopathy)

**Specific Antidotes Due to Cellular or Mitochondrial Poisons**
- Carbon monoxide
- Methemoglobinemia
- Hydrogen sulfide
- Cyanide

The second phase of organ injury from hemorrhagic shock occurs during resuscitation. The acute phase of hemorrhage initiates the inflammatory cascade, and resuscitation unleashes these volatile inflammatory mediators on the body, inducing organ injury. During resuscitation, neutrophils become more aggressive, binding to the lung endothelium and causing capillary leakage that characterizes acute respiratory distress syndrome (ARDS). Inflammatory cytokines are liberated, causing additional cellular damage and compounded by persistent microischemia in numerous organs due to an imbalance between vasodilation by nitric oxide (NO) and vasoconstriction by endothelins. The liver demonstrates centrilobular injury, demonstrated clinically by elevated transaminase levels, whereas the kidney may manifest acute spasm of the preglomerular arterioles, with resultant acute tubular necrosis. A growing body of evidence has suggested that resuscitation from hemorrhage exerts greater injury on the heart than the actual hypotensive insult.

**Septic Shock**

Although historically presented as the archetype of vasogenic or distributive shock, in reality the clinical course of septic shock is much more complex and varies over the course of the disease, with variables degrees of intravascular volume depletion, peripheral vasodilatation, and impaired cardiac function. Septic shock can be produced by infection with any microbe, although in half or more of cases of septic shock, no organism is identified. One well-known mediator of sepsis is lipopolysaccharide (LPS), contained in the outer cell membrane of gram-negative bacteria; however, gram-positive organisms are now the primary cause of sepsis in hospitalized patients, indicating that the pathophysiology of sepsis cannot be explained simply by the response to LPS.

Septic shock often causes three major effects that must be addressed during resuscitation—hypovolemia, cardiovascular depression, and induction of systemic inflammation. Septic shock produces relative and absolute hypovolemia, reducing right ventricular filling. Absolute hypovolemia results from gastrointestinal volume loss, tachypnea, sweating, and decreased fluid intake during development of the illness. Further relative hypovolemia results from increased venous capacitance in conjunction with increased capillary leak and resultant loss of intravascular volume into third spaces. Septic shock causes direct myocardial depression. Measurements of cardiac contractility have shown that mechanical function becomes impaired early in the course of septic shock, even in the hyperdynamic stages. Circulating mediators, myocardial cellular injury from inflammation, and deranged metabolism interact synergistically to injure the heart during septic shock, and specific cytokines (most notably tumor necrosis factor alpha [TNF-α] and interleukin-1 beta [IL-1β]), overproduction of NO by inducible nitric oxide synthase (iNOS), and possibly impairment in mitochondrial oxidative phosphorylation, may all play a role. Similar to hemorrhagic shock, systemic inflammation causes capillary leak in the lung, resulting in ARDS. Widespread systemic inflammation likely plays a role in the development and persistence of multisystem organ failure in sepsis through microvascular and mitochondrial dysfunction. Clinical trials to date have yet to demonstrate the effectiveness of specific or general antiinflammatory therapies in mitigating this response, and the treatment of septic shock relies primarily on the reversal of shock, supportive care, and source control.
Cardiogenic Shock

Cardiogenic shock results when more than 40% of the myocardium becomes dysfunctional from ischemia, inflammation, toxins, or immune injury. Otherwise, cardiogenic shock essentially produces the same circulatory and metabolic alterations as those that are observed with hemorrhagic shock. Undoubtedly, impaired baseline cardiac function can contribute to the development of circulatory shock secondary to infection, hemorrhage, or vasodilatory drug overdose. However, when shock results from a pure cardiac cause, severe left ventricular dysfunction will be evident on echocardiography early in the course. Patients with severe underlying dysfunction are far more likely to have a cardiogenic cause of shock than patients with normal or moderate left ventricular dysfunction.

Neurogenic Shock

Neurogenic shock results from interrupted sympathetic and parasympathetic input from the spinal cord to the heart and peripheral vasculature, typically resulting from acute traumatic injury. Traditionally, it has been described as peripheral vasodilation in conjunction with bradycardia. However, ED patients with shock from acute spinal injury actually manifest a range of heart rates and peripheral vascular resistance, most likely due to variable location of injury and the balance between disrupted efferent sympathetic and parasympathetic tone. As a result, no single presentation adequately summarizes patients with neurogenic shock. It is likely that the downstream pathophysiologic consequences of persistently impaired perfusion mimic those of cardiogenic and hemorrhagic shock.

**MANAGEMENT**

**Decision Making**

Patients presenting to the ED in shock frequently have no obvious cause. Rapid recognition of shock requires the integration of information from the immediate history and physical examination and is strongly supported by the presence of a worsening base deficit or lactic acidosis. In general, patients with shock exhibit a stress response; they are ill appearing, asthenic, pale, often sweating, usually tachypneic, and often have a weak and rapid pulse (Box 6.2). In all patients with shock, HR, BP, and oxyhemoglobin saturation are continuously monitored. HR can be normal or low in shock, especially in cases complicated by prescribed drugs that depress HR. BP initially can be normal because of adrenergic input from the spinal cord to the heart and peripheral vasculature, typically resulting from acute traumatic injury. It is likely that the downstream pathophysiologic consequences of persistently impaired perfusion mimic those of cardiogenic and hemorrhagic shock.

**Critical Management Principles**

A systematic ultrasound protocol can significantly improve the management. Patients with prehospital hypotension, whether toxic shock or systemic sepsis, generally demonstrate a normal BP until they rapidly deteriorate.

**Urine output** provides an excellent indicator of vital organ perfusion and is readily available with insertion of a Foley catheter. Measurement of urine output, however, requires 30 to 60 minutes for accurate determination of whether output is normal (>1.0 mL/kg/h), reduced (0.5–1.0 mL/kg/h), or severely reduced (<0.5 mL/kg/h), and is of limited use in patients with preexisting renal disease. Arterial or venous lactate concentration and the base deficit provide accurate assessment of global perfusion status. A lactate concentration greater than 4.0 mM or base deficit more negative than –4 mEq/L indicates circulatory insufficiency severe enough to cause subsequent multiple organ failure. A downward trend of the serum lactate concentration or upward trend of the base deficit, with correspondingly improving vital signs and urine output, reliably gauge the adequacy of resuscitation and prognosis in shock from any cause. A rising lactate concentration (or refractory hypotension, with worsening base defect), despite ongoing resuscitation, calls for more intensive measures. Once the empirical criteria for circulatory shock have been discovered, the next step is to consider the cause of the shock. Fig. 6.1 shows a potential sequence of decisions to help arrive at a diagnosis in a patient with undifferentiated shock.

The history, vital signs, and physical examination documented by prehospital providers can be useful in ED evaluation and management. Patients with prehospital hypotension, whether of medical or traumatic origin, have up to a fourfold higher in-hospital mortality rate than patients without hypotension.

On physical examination, dry mucous membranes suggest dehydration, whereas jugular venous distention suggests congestive cardiac failure or right ventricular strain from pulmonary embolism (PE). Muffled heart sounds with jugular venous distention suggest cardiac tamponade, whereas a loud, machine-like, systolic murmur indicates acute rupture of a papillary muscle or interventricular septum. Diffuse ronchi suggest bronchospasm, cardiac failure, or PE. Abdominal tenderness may indicate peritonitis, intestinal perforation, or occult trauma. The presence of melena or bright red stools on rectal examination indicates gastrointestinal hemorrhage. The neurologic examination documents responsiveness, cognition, and presence of any focal deficits and can be a means of clinically assessing end-organ perfusion. In children, documentation should include response to parents, appropriateness of crying, symmetry of grimace, symmetry of extremity movements, and motor tone.

Laboratory, radiographic, and other ancillary data can be useful to assess tissue and vital organ perfusion and diagnose injury from trauma, find the source of infection with sepsis, or identify the cause of cardiac failure. Chest radiography, electrocardiography, finger stick glucose measurement, complete blood count (CBC), urinalysis, serum electrolyte levels, and kidney and liver function tests are indicated for most patients with suspected shock. Arterial blood gas determination provides the base deficit and allows correlation of arterial gas tensions (PaO₂ and PaCO₂) with those measured by pulse oximetry and capnography. Serum lactate level measurement is performed as early as possible in patients with suspected shock; venous or arterial lactate concentrations can be used. If the peripheral venous lactate level is used, the effect of time, storage temperature, and tourniquet use have no significant effect if the measurement is done within 15 minutes after the sample was obtained. Cardiac and abdominal bedside ultrasound scanning can screen for inadequate central venous volume, occult hemoperitoneum, abdominal aortic aneurysm, left ventricular failure, and cardiac tamponade.

A systematic ultrasound protocol can significantly improve the

**BOX 6.2**

**Empirical Criteria for Diagnosis of Circulatory Shock**

- Ill appearance or altered mental status
- Heart rate > 100 beats/min
- Respiratory rate > 20 breaths/min or PaCO₂ < 32 mm Hg
- Arterial base deficit < –4 mEq/L or lactate level > 4 mM/L
- Urine output < 0.5 mL/kg/h
- Arterial hypotension > 30 min duration, continuous

* Regardless of cause. Four criteria should be met.
Definitions and Criteria for Septic, Hemorrhagic, and Cardiogenic Shock

**SEPTIC SHOCK**
Systemic Inflammatory Response Syndrome (SIRS)
Two or more of the following:
1. Temperature > 38°C or < 36°C
2. Heart rate > 90 beats/min
3. Respiratory rate > 20 breaths/min or PaCO₂ < 32 mm Hg
4. White blood cell count > 12,000/mm³, < 4,000/mm³, or > 10% band neutrophilia

**Septic Shock**
SIRS with suspected or confirmed infection and associated with organ dysfunction or hypotension; organ dysfunction may include presence of lactic acidosis, oliguria, and/or altered mental status.

**HEMORRHAGIC SHOCK**
Simple Hemorrhage
Suspected bleeding with pulse rate < 100 beats/min, normal respiratory rate, normal blood pressure, and normal base deficit

**Hemorrhage with Hypoperfusion**
Suspected bleeding with base deficit < −6 mEq/L or persistent pulse rate > 100 beats/min

**CARDIOGENIC SHOCK**
Cardiac Failure
Clinical evidence of impaired forward flow of the heart, including presence of dyspnea, tachycardia, pulmonary edema, peripheral edema, and/or cyanosis

**Cardiogenic Shock**
Cardiac failure plus four criteria listed in Box 6.2

---

**Box 6.5**

**FIG. 6.1.** Flow diagram to classify undifferentiated shock.

Consensus definitions of shock show the spectrum of hypoperfusion for the following three common causes of shock (Box 6.3):

1. **Hemorrhagic shock.** The American College of Surgeons has divided hemorrhagic shock into four stages, depending on the severity of blood loss and physiologic response to this loss, but such arbitrary divisions are of little value and are not accurate reflections of degree of hemorrhage in clinical practice. A more useful approach defines hemorrhagic shock as being present when systemic hypoperfusion manifests as lactic acidosis or increasing base deficit with concomitant organ dysfunction.

2. **Septic shock.** International consensus definitions distinguish septic shock from its precursor conditions—systemic inflammatory response syndrome (SIRS), sepsis, and severe sepsis. SIRS is often a precursor of shock, but the nonspecific criteria for SIRS are found in a large variety of conditions, many of which are benign, so the clinical context is vital to understanding the significance of these physiologic variations. Although a consensus definition of septic shock requires persistent hypotension after fluid resuscitation, initiation of treatment for empirically diagnosed severe sepsis or septic shock should not await the onset of hypotension. The incorporation of an indicator of tissue hypoperfusion (Box 6.4) into the clinical assessment may improve identification of hypoperfusion, particularly in subtle cases.

3. **Cardiogenic shock.** Cardiogenic shock should be thought to be present whenever cardiac failure (ischemic, toxic, or obstructive) causes systemic hypoperfusion that manifests as lactic acidosis with organ dysfunction.

Box 6.5 presents the general treatment approach for these three common causes of shock.
Monitoring Perfusion Status

Patients with cardiac failure or renal failure may benefit from closer measurement of dynamic variables of fluid responsiveness that can be measured from an arterial line (eg, stroke volume variation or stroke volume index) or a central venous line (central venous pressure [CVP]). A triple-lumen catheter allows for accurate measurement of the CVP, although the clinical utility of these measurements has been debated. However, a triple-lumen catheter also allows for safe infusion of vasopressors in hypotensive patients unresponsive to an initial fluid bolus, as well as more rapid simultaneous infusion of intravenous (IV) fluids and antibiotics in patients with limited IV access. In children, a 3- or 5-Fr 3-bilumen catheter can be placed in the femoral vein with few complications. If unable to attain adequate peripheral or central venous access rapidly in patients with shock, intraosseous (IO) access should be established, because it is easy and can provide a temporary method of administering fluid resuscitation and medications to adults and children. However, IO access should be considered a bridge to definitive IV access due to the risk of complications with prolonged usage in the inpatient setting. If vasoactive medications are administered, additional peripheral IV catheters will be required for infusion of crystalloid and other treatments. Many patients with renal disease or cancer have indwelling catheters in place. In patients with empirical criteria for shock, this catheter should be used for IV access, unless satisfactory access has already been established at other anatomic sites. In EDs where the standard practice is not to use these ports at the request of other emergency clinicians, a specific hospital policy and training session should be developed to make an exception in the case of circulatory shock. In general, failure to administer fluids rapidly and in sufficient quantity outweighs considerations about preservation of the line for future therapy.

**Quantitative Resuscitation**

Quantitative resuscitation, also called goal-directed therapy, goal-oriented resuscitation, or hemodynamic optimization, was first described in 1988 and refers to the practice of resuscitating patients to predefined physiologic endpoints indicating that systemic perfusion and vital organ function have been restored. Since that time, many studies have evaluated the efficacy of such a therapeutic approach to shock and have confirmed its benefit for reducing mortality. For many years, in the intensive care unit (ICU), clinicians have relied on the use of the pulmonary artery catheter to help optimize left ventricular filling indices, but data supporting the efficacy of this practice on patient-centered outcomes such as mortality are lacking. There is insufficient evidence to support the use of pulmonary artery catheters for ED patients, and their significant complication rate, in the context of uncertain or no benefit, leads us to recommend against their routine use.

Lactate clearance refers to serial measurements of the venous or arterial lactate level and is calculated according to the following formula:

\[
(\text{Lactate}_{\text{initial}} - \text{Lactate}_{\text{delayed}}) / \text{Lactate}_{\text{initial}} \times 100
\]

Lactate clearance has been shown to be equivalent to central venous oxygen saturation as an endpoint of early septic shock resuscitation. Lactate clearance measurements are easily obtained from peripheral venous blood and are a preferred endpoint of resuscitation. If the lactate concentration has not decreased by 10% to 20% 2 hours after resuscitation has begun, additional steps are undertaken to improve systemic perfusion. Resuscitation should continue until the lactate concentration drops below 2 mM/L.

Mixed venous oxygen saturation ($SvO_2$) measurements reflect the balance between oxygen delivery and oxygen consumption. The $SvO_2$ can be used as a surrogate for CI—targeting an $SvO_2$ of 65% is equivalent to reaching a CI of 2.5–3.5 L/min/m²—as a therapeutic endpoint in critically ill patients. Although $SvO_2$ requires the use of a pulmonary artery catheter, the central venous oxygen saturation ($ScvO_2$) drawn from the central circulation has been shown to parallel changes or trends over time and is the
preferable method for pulmonary artery catheter placement in the ED.

Quantitative resuscitation, which incorporates multiple indices of circulatory and oxygenation status, has been shown in meta-analyses to reduce mortality and morbidity in ED patients with severe sepsis or septic shock significantly when instituted as early in the disease course as is practical. In such an approach, patients are resuscitated early, within the first 6 hours, to achieve normalization of markers of volume status, perfusion, and adequate oxygen delivery (Fig. 6-2). The first description of an ED-based quantitative resuscitation strategy targeted specific volume, perfusion, and oxygen delivery endpoints and was termed early goal-directed therapy (EGDT). Recently, three large multicenter trials did not demonstrate a mortality advantage for patients receiving EGDT as compared to the appropriate volume resuscitation and targeted therapies that constitute the current usual care of shock. Patients in these studies received 2 to 4 L early volume resuscitation and relatively prompt antibiotic administration, suggesting that early recognition and initiation of fluid and antibiotic therapy, in conjunction with close monitoring and thoughtful care, may be more important than the use of invasive measurements to attain the specific resuscitation goals suggested by earlier studies.

**Pharmacology**

**Volume Replacement**

Most patients with shock can be fully resuscitated with peripheral venous access established with at least two 18-gauge two catheters. The goal in volume replacement is slightly elevated left ventricular end-diastolic volume, which is difficult to measure in the ED. Historically, CVP has been used to estimate right ventricular filling pressure and is used in some quantitative resuscitation algorithms. However, CVP measurement does not accurately reflect left ventricular end-diastolic volume, and CVP poorly predicts the hemodynamic response to a fluid challenge. Thus, assessment of fluid responsiveness and fluid resuscitation should not be based solely on CVP. A better approach would include the use of the clinical response to fluid resuscitation, such as increases in urine output, BP, and decreasing lactate concentrations, alone or in combination with CVP measurements. In patients for whom fluid resuscitation may be associated with higher risk of harm (eg, severe systolic heart failure), the use of dynamic variables of fluid responsiveness that can be measured from an arterial line (eg, stroke volume variation, stroke volume index, passive straight leg raise) may be beneficial over empirical fluid boluses, but their use in the ED has not been studied.

**Crystalloids.** Standard treatment for hemorrhagic shock historically consisted of rapidly infusing several liters of isotonic crystalloid in adults or three successive 20-mL/kg boluses in children. Recent studies have endorsed the concept of delayed resuscitation or hypotensive resuscitation for hemorrhagic shock (see Chapter 33). No study to date has demonstrated the survival benefit of one type of crystalloid versus another; therefore, the choice of fluids may be less important than scrupulous monitoring for adequate tissue perfusion. Although a single Australian study has suggested an association between use of chloride-rich solutions and subsequent renal dysfunction in ICU patients, the study solutions included colloids as well as crystalloids and were not randomized, so any causative inference is not justified. Normal saline or lactated Ringer’s solution may be used for volume replacement during resuscitation, with no evidence clearly supporting one over the other. Accordingly, the selection of isotonic crystalloid solution may be based on institutional, departmental, or individual preferences. Initial volume replacement consists of the rapid infusion of 20 to 25 mL of isotonic crystalloid per kilogram.

**Colloids and Hypertonic Saline.** Colloids, including albumin, have been used in patients with hemorrhage, but at considerable increase in cost and without effect on morbidity or mortality. Colloids offer the theoretic advantage of a high osmotic pressure, which should help maintain normal intravascular volume. Initial resuscitation fluid treatment with hypertonic saline or hypertonic saline and dextran, compared with normal saline, has not been found to result in superior 28-day survival.

In the setting of septic shock, initial fluid resuscitation should consist of serial boluses of IV isotonic crystalloid as long as the patient continues to demonstrate a positive hemodynamic response to fluid loading. Persistent hypotension, despite 30 mL/kg of IV fluid, indicates the need to add vasopressors to the resuscitation (see below). If patients require large volumes of crystalloid (>4 L), we recommend adding 5- to 10-mL/kg boluses of a natural colloid (eg, albumin), rather than additional isotonic crystalloid alone, until volume responsiveness is achieved. We do not recommend use of synthetic colloids, such as hydroxyethyl starch, which have recently been demonstrated to be associated with a higher risk of renal failure. The infusion of hemoglobin-based blood substitutes as alternatives to packed red blood cells (PRBCs) for the resuscitation of hemorrhagic shock has been extensively studied and is associated with significant increased risk of death and myocardial infarction; we recommend against their use.

**Blood Products.** In the setting of hemorrhage or a critically low hemoglobin level (<7 g/dL), if criteria for shock persist despite crystalloid infusion (see Box 6.2), we recommend transfusion of PRBCs (1–2 units in adults or 5–10 mL/kg in children). Fully crossmatched blood is safest and is always preferable unless the patient’s need is considered sufficiently urgent to justify the use of type-specific or even uncrossmatched blood. Use of the latter is generally confined to patients with hemorrhagic shock with persistent, severe, arterial hypotension and massive or uncontrollable hemorrhage. O-negative blood is used in women of childbearing age, and O-positive blood is used in all others (see Chapter 11). If patients require more than 2 units of PRBCs for hemorrhage, we recommend a balanced resuscitation using PRBCs, fresh-frozen plasma, and platelets in a 1:1:1 ratio, which is associated with better hemostasis and lower death due to exsanguination by 24 hours. The goal hemoglobin target for patients with septic shock in the acute resuscitation window, generally defined as the first 6 hours following presentation, remains controversial. A recent large randomized controlled trial (RCT) in ICU patients with septic shock found similar rates of ischemic events, use of life support, and 90-day mortality among patients transfused at a threshold of 7 g/dL, as compared to 9 g/dL. Thus, we recommend transfusion of PRBCs at a threshold of 7 g/dL in patients with septic shock unless specific contraindications exist or patients refuse transfusion.

**Vaspressors**

The primary goal of vasopressor support is to increase cardiac output and oxygen delivery to vital organs when crystalloid resuscitation alone is inadequate. To reduce the potential for limb damage from extravasation from a peripheral IV injection, vasopressors are optimally administered through a central venous catheter, although this is not always feasible in the acute setting. Patients with septic shock who remain hypotensive after...
Fig. 6.2. Flow diagram outlining an example of a formalized resuscitation strategy. This figure illustrates the sequential targeting of preload, afterload, oxygen supply, and demand matching for sepsis-induced hypoperfusion. The protocol outlines specific hemodynamic and physiologic parameters that the emergency clinician should seek to attain within the first 6 hours of care. This protocol is focused on resuscitation and should be used in conjunction with standard clinical care for patients with suspected infection, such as appropriate diagnostic studies, to determine the focus of infection and appropriate antimicrobial agents to treat the infection. *HCT,* Hematocrit; *ICU,* intensive care unit; *IJ,* internal jugular; *INR,* international normalized ratio; *MAP,* mean arterial pressure; *NS,* normal saline; *Paco₂,* partial pressure of carbon dioxide, arterial; *Sat,* peripheral oxygen saturation; *SBP,* systolic blood pressure; *SC,* subclavian; *ScvO₂,* central venous oxygen saturation; *SIRS,* systemic inflammatory response syndrome; *WBC,* white blood cell count.
a 30-mL/kg fluid bolus generally require vasopressor support. Several randomized trials and a meta-analysis have suggested that norepinephrine (5–30 μg/min) is associated with improved efficacy and lower rates of adverse effects, making norepinephrine the vasopressor of choice for correction of hypotension in septic shock. In patients who remain in shock after initial crystalloid boluses, norepinephrine should be initiated at a rate of 0.05 μg/kg/min and titrated at 3- to 5-minute intervals until the mean arterial pressure is greater than 65 mm Hg or the systolic BP is greater than 90 mm Hg. There are no clear data regarding an absolute maximum dose, but generally there is little or no additional pressor effect once a dose of 30 μg/min has been reached. Vasopressin can be added as a second vasopressor agent when norepinephrine reaches the maximum dose of 30 μg/min. Vasopressin should be administered at a fixed rate of 0.03 to 0.04 units/min and should not be titrated. A trial of vasopressin cessation can be attempted once the patient demonstrates improving hemodynamics over at least a 6-hour period. Except in cases of a prolonged stay in the ED, vasopressors will not be stopped until the patient is in the ICU. Following vasopressor initiation, particularly in patients who require high or rapid upward titration of the vasopressor dose, patients should be reassessed for their responsiveness to additional fluid boluses through the use of dynamic variables or empirical 500-mL boluses, with careful attention to the clinical response. Vasopressor support, along with crystalloid therapy, is continued until the patient can maintain the blood pressures listed without vasopressor support, which can be tested at the bedside by weaning the vasopressor agent at a rate of 2 to 3 μg/min every 5 to 10 minutes.

Inotropes

Dobutamine may also be used with norepinephrine to increase cardiac output and maintain adequate oxygen delivery in cardiogenic and septic shock. In the setting of cardiogenic shock, dobutamine may be indicated by some combination of hypotension, cool extremities, poor urine output, and elevated lactate level. In the setting of septic shock, if the lactate level does not decrease at least 10% and/or the measured S\textsubscript{C\textsubscript{O\textsubscript{2}}} does not reach 70%, despite fluid resuscitation and vasopressor administration (see earlier), dobutamine can be added at a dose of 2 μg/kg/min and titrated every 5 to 10 minutes, to a maximum of 20 μg/kg/min. Due to stimulation of vasodilating peripheral beta receptors, dobutamine does have the potential to decrease the BP, so careful attention to a patient’s individual response is necessary. If simultaneous BP and inotropic support is necessary for septic shock, epinephrine alone, 0.2 μg/kg/min starting dose, provides similar outcomes and adverse event rates as a combination of norepinephrine plus dobutamine. When norepinephrine is the first pressor initiated and an inotrope is indicated, we recommend the addition of dobutamine, with the ability to titrate each agent individually. However, it is acceptable as an alternative to discontinue the norepinephrine and initiate epinephrine infusion to provide vasopressor and inotropic support via a single agent.

Antimicrobial Therapy

Treatment of the infection with antimicrobial therapy and, where necessary, surgical drainage (see later, “Source Control”), should be instituted as soon as practical in cases of septic shock. Current evidence does not support an absolute time requirement for administration but, when septic shock is the working diagnosis in the ED, we recommend initiation of appropriate antibiotics as soon as practical after the diagnosis is made, ideally within 4 hours of ED presentation. When there is no focus of infection identified in a patient with presumed septic shock, a semisynthetic penicillin with a β-lactamase inhibitor, in combination with a fluoroquinolone and vancomycin, is a rational empirical choice. One such regimen would include piperacillin-tazobactam, 4.5 g IV every 6 hours, plus levofloxacin, 750 mg IV every 12 hours, and vancomycin, 30 mg/kg (maximum dose, 2 g) given every 12 hours, adjusted as appropriate for trough levels and renal failure.

Patients with neutropenia and sepsis syndrome are at particular risk for progressive sepsis, organ failure, and death. Neutropenia can be suspected in patients who have recently undergone chemotherapy, and these patients often know that they are neutropenic. Antimicrobial administration is particularly urgent for these patients and should occur rapidly after blood cultures are obtained, in parallel with crystalloid administration. Antibiotic considerations for the neutropenic patient are discussed in Chapter 115. Chemotherapy patients with sepsis represent a special challenge because the pathophysiology may be complicated by anemia, thrombocytopenia, dehydration from vomiting, and the effects of adjunctive steroid therapy. Chemotherapy patients often have indwelling catheters, which predispose them to more unusual causes of sepsis, including gram-positive bacteria and fungi (see Chapters 115 and 187).

Corticosteroids

There is no evidence for high-dose, short-course corticosteroid therapy in unselected patients with septic shock. Most current guidelines recommend that low-dose hydrocortisone be administered only to patients receiving chronic steroid replacement and in patients with refractory shock, despite adequate fluid and vasopressor support. Even this is only marginally supported, if at all, by scientific evidence. Corticotropin stimulation testing is no longer considered of value.

Special Cases

Systemic thrombolytic therapy is indicated in patients with shock from pulmonary embolism (see Chapter 78) without contraindications. Specific treatments for shock as a result of poisoning with vasoactive medications and other toxins are discussed in the relevant chapters in this text.

Devices and Procedures

Ventilation

Rapid sequence intubation is the preferred method of airway control in most patients with refractory shock (see Chapter 1). Tissue hypoperfusion leads to increasing fatigue of the muscles of respiration, and respiratory failure commonly supervenes in patients with persistent shock. Intubation prevents aspiration, increases oxygenation, treats acute respiratory failure, provides initial treatment for metabolic or hypercarbic acidemia, and protects the patient who will be sent to an uncontrolled environment (eg, for testing). Intubation also reduces the work of breathing, which, in the patient with hypoperfusion, further exacerbates lactic acidemia. Strenuous use of accessory respiratory muscles can increase oxygen consumption by 50% to 100% and decrease cerebral blood flow by 50%. More importantly, if the patient has increased airway resistance (eg, bronchospasm with anaphylaxis) or a decrease in lung compliance (eg, pulmonary edema, ARDS), a more negative intrathoracic pressure must be generated to fill the lungs with each inspiration. The greater suction effect is also exerted on the left ventricle, impeding its ability to eject and increasing functional afterload. Positive-pressure ventilation removes this impedance and can improve ventricular function and cardiac output up to 30%. The use of etomidate for patients with septic shock is discussed in Chapter 1.
Part I  Fundamental Clinical Concepts  |  Section One  Critical Management Principles

Source Control

Controlling hemorrhage remains the cornerstone of treating hemorrhagic shock, and evidence continues to support immediate surgery when direct vascular control cannot otherwise be obtained (see Chapters 33 and 41). Gastrointestinal bleeding may require urgent endoscopy, often in the ED or ICU, and aortic rupture requires emergency consultation by a vascular surgeon. In septic shock related to an abscess, aggressive infection (eg, necrotizing fasciitis; see Chapter 129) or wound (eg, toxic shock syndrome; see Chapter 130), removal of the infectious stimulus through surgical intervention should proceed as soon as practical.

Intraaortic Balloon Pumps and Percutaneous Coronary Intervention

The use of intraaortic balloon counterpulsation and percutaneous coronary intervention in selected patients with cardiogenic shock or acute cardiovascular emergencies is discussed in Chapter 68.

Pericardiocentesis and Thrombectomy

Shock caused by mechanical obstruction can be managed by direct intervention. Large, acute pericardial effusions should be managed with pericardiocentesis. Surgical thrombectomy for massive pulmonary embolism is performed rarely. Direct thrombolysis via interventional radiology, however, has been gaining acceptance as a therapeutic option in patients with shock, particularly if systemic thrombolytics are contraindicated.

Outcomes

Outcomes for patients with shock vary with the underlying cause of the shock state and the premorbid or comorbid status of the patient. Outcomes have progressively improved, with emphasis on early diagnosis and treatment. In general, persistent hypotension (refractory shock) is associated with worse outcomes. Patients meeting consensus definitions for hemorrhagic shock have a mortality rate of about 20%, whereas this exceeds 40% in septic and cardiogenic shock.

KEY POINTS

- Circulatory shock can occur with normal arterial blood pressure, and not all patients with arterial hypotension have circulatory shock.
- A base deficit more negative than $-4 \text{ mEq/L}$ or a serum lactate level greater than 4.0 mmol/L warrants a presumptive diagnosis of shock.
- Urine output is a reliable index of vital organ perfusion in patients with suspected shock. Normal urine output is 1.0 mL/kg/h. Output less than 0.5 mL/kg/h indicates severe renal hypoperfusion.
- A combination of a worsening base deficit, increasing lactate level, and low urine output represents persistent or worsening circulatory shock.
- Early initiation of fluid resuscitation, with pressor support as needed, and appropriate antimicrobial therapy improve the outcomes in patients with septic shock.
- The use of defined physiologic endpoints to measure systemic perfusion during resuscitation (quantitative resuscitation) improves outcomes for ED patients with shock.

CHAPTER 6: QUESTIONS & ANSWERS

6.1. Which of the following is considered one of the empirical criterion for the diagnosis of circulatory shock?

A. Partial pressure of carbon dioxide (Paco₂) < 40 mm Hg
B. Partial pressure of oxygen (Pao₂) < 55 mm Hg
C. Serum lactate level < 4 mM/L
D. Systolic blood pressure (SBP) < 100 mm Hg
E. Urine output < 0.5 mL/kg/h

Answer: E. Four of the following criteria should be met for the diagnosis of circulatory shock:

1. Ill appearing or altered mental status
2. Heart rate > 100 beats/min
3. Respiratory rate > 20 breaths/min or Paco₂ < 32 mm Hg
4. Arterial base deficit < −4 mEq/L or lactate level > 4 mM/L
5. Urine output < 0.5 mL/kg/h
6. Arterial hypotension > 20 min duration

6.2. Which of the following, when present and in the setting of suspected or confirmed infection, helps distinguish severe sepsis from systemic inflammatory response syndrome (SIRS) with suspected or confirmed infection and associated with organ dysfunction or hypotension. The organ dysfunction mentioned may include the presence of lactic acidosis, oliguria, and/or altered mental status. The diagnosis of SIRS is made when two or more of the following are present:

1. Temperature > 38°C or < 36°C
2. Heart rate > 90 beats/min
3. Respiratory rate > 20 breaths/min or Paco₂ < 32 mm Hg
4. White blood cell count > 12,000/mL, < 4,000/mL, or > 10% band neutrophilia

Answer: A. Dobutamine
B. Dopamine
C. Norepinephrine
D. Hematocrit
E. Packed red blood cell (PRBC) transfusion

6.3. An 18-year-old unrestrained driver is transported to the emergency department (ED) after being thrown from his vehicle during a motor vehicle collision. He was intubated in the field and received an intravascular bolus of 3 L of normal saline before arrival to the ED. His initial Glasgow Coma Score (GCS) is 7, and his blood pressure on arrival is 80/50 mm Hg. Which of the following would be the most appropriate to initiate immediately on arrival to the ED?

A. Dobutamine
B. Dopamine
C. Norepinephrine
D. Hematocrit
E. Packed red blood cell (PRBC) transfusion

Answer: E. In patients with signs of hemorrhagic shock and suspected central nervous system trauma or GCS < 9, immediate PRBC transfusion should be initiated. This assists with volume expansion and oxygen delivery to the brain. Pressors and positive inotropes will be of little benefit before volume replacement, and hetastarch has no proven benefit for initial resuscitation in head injury patients.
CHAPTER 7

Brain Resuscitation

Craig A. Williamson | William J. Meurer

PRINCIPLES

Background

Despite our recognition of the brain’s dominant role in determining the quality of life, modern medicine’s ability to intervene and reverse neuronal injury remains limited. Consequently, modern techniques of brain resuscitation are focused on restoring cerebral homeostasis and mitigating the effects of secondary brain injuries. Hypoxic-ischemic injury following cardiac arrest can be seen as a model of global ischemic disease, and recent advances in understanding of its pathophysiologic mechanisms have led to improvements in neurologic outcomes. Although hypoxic-ischemic injury represents a so-called pure form of brain ischemia, its underlying pathology has significant overlap with other cerebral injuries, such as stroke and traumatic brain injury. Thus, many of the physiologic principles of brain resuscitation following cardiac arrest are applicable to these conditions. This chapter, therefore, reviews the pathophysiology of ischemic brain injury and discusses therapies for improving neurologic recovery following cardiac arrest and other critical neurologic illnesses in which cerebral ischemia may occur.

Anatomy, Physiology, and Pathophysiology

The human brain consists of 10 billion neurons, each with multiple connections to other cells, totaling an estimated 500 trillion synapses. Although the brain constitutes only 2% of body weight, it receives 15% of the body’s cardiac output and accounts for 20% of the body’s overall oxygen use. Although no mechanical or secretory work is performed by the brain, energy expenditures include the synthesis of cellular constituents (eg, an estimated 2000 mitochondria are reproduced each day by each cell) and neurotransmitter substances, axoplasmic transport of these substances, and transmembrane pumping of ions.

When the brain is deprived of adequate blood flow, the resulting ischemia is characterized by a bewildering array of interrelated physiologic and cellular responses that ultimately result in neuronal cell death (Fig. 7-1). Although this complex cascade of events can be triggered by periods of ischemia lasting only a few minutes, the resulting neuronal death is usually delayed by hours or days. Furthermore, the biology of cerebral cell death after global cerebral ischemia follows the pattern of delayed cerebral cell death that follows stroke, traumatic brain injury, and other forms of hypoxic or toxic brain injury, with slight variations. Increased understanding of the brain’s response to injury during the period between insult and neuronal cell death will eventually allow more specific brain resuscitation therapies.

Elevated Intracranial Pressure

Intracranial pressure (ICP) is an important consideration in ischemic brain injury because cerebral ischemia can directly result in ICP elevation. This occurs because the failure of oxidative phosphorylation depletes adenosine triphosphate (ATP) stores, which results in an inability to maintain osmotic gradients actively. Increased intracellular osmolarity leads to water influx and the development of cytotoxic edema, which usually peaks 48 to 72 hours after injury. By decreasing cerebral perfusion pressure (CPP), elevated ICP is also an important contributor to secondary brain injury. This relationship is discussed in further detail below; additional information on ICP management is contained in the pharmacology, devices, and techniques sections.

To understand the pathophysiologic of elevated ICP, it should be noted that the skull is a rigid container whose relatively noncompressible contents include the brain (~80%), blood (~10%), and cerebral spinal fluid (CSF; ~10%). According to the Monro-Kellie hypothesis, any addition to the volume of one of these components—for example, increased brain volume due to cerebral edema—must be offset by a reduction in the volume of the other contents or the ICP will rise.

Typically, adaptation to increased intracranial volume is initially accomplished by shifting CSF from the intracranial to spinal subarachnoid compartment. Approximately two-thirds of cerebral blood volume is contained in the cerebral veins and dural sinuses, and this venous capacitance can be reduced to accommodate increased intracranial volume further. Unfortunately, these mechanisms are sometimes quickly exhausted, resulting in decreased compliance and a significant increase in ICP. This may occur rapidly with acute cerebral injury or slowly with mass lesions such as tumors.

In its final stages, uncontrolled intracranial hypertension will result in downward herniation of the cerebellar tonsils through the foramen magnum, thereby compressing critical cardiorespiratory centers in the medulla. Prior to or concurrently with this, elevated ICP can exacerbate ischemic injury by reducing cerebral blood flow. CPP is equal to the mean arterial pressure (MAP) minus ICP. As ICP increases, CPP decreases, which is compensated for by cerebral arteriolar vasodilation. Unfortunately, this vasodilation may increase cerebral blood volume, which can additionally increase ICP and further reduce CPP. This vicious cycle is one of the primary inciting factors for the prolonged periods of refractory ICP elevation known as plateau or Lundberg A waves.

MANAGEMENT

Decision Making

Standard management of ischemic brain damage involves restoring cerebral blood flow (CBF) and preventing secondary insult. Most treatments have not been studied in prospective, randomized, controlled trials, but have been supported by clinical experience and limited experimental data. Although proposed and experimental neuroprotectant therapies are generally aimed at specific molecular interventions in the pathophysiology of ischemic brain injuries, as yet none of these have proven effective in clinical trials. In the case of ischemic injury following cardiac arrest, the most comprehensive review and consensus guideline statement on care of patients with post–cardiac arrest syndrome
has come from the International Liaison Committee on Resuscitation and its constituent bodies, with the endorsement of the American College of Emergency Physicians, Society for Academic Emergency Medicine, Society of Critical Care Medicine, and Neurocritical Care Society. Improvements in post–cardiac arrest care, through an inclusive multisystem approach, can increase the likelihood of meaningful recovery in these patients. Implementation of standardized protocols for postresuscitation care that include many or all of the following components have demonstrated increases in survival, with a favorable neurologic outcome of up to 30% in repeated (although poorly controlled) before and after studies.

---

**Fig. 7.1.** Synopsis of events contributing to neuron cell death cascade after ischemia. A, Decreased cerebral flow (CBF) and arterial oxygen content during ischemia cause decreased adenosine triphosphate (ATP) production, failure of ATP-driven ion pump efflux of potassium ions (K+), and influx of sodium ions (Na+) and calcium ions (Ca2+) through voltage-gated channels. ADP adenosine diphosphate. B, Na+ influx causes depolarization and glutamate (Glu) release, opening Glu receptor α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and kainate (KA) channels and exacerbating intracellular Na+ overload. Increased Na+ concentration ([Na+]i) leads to cytotoxic edema. Glu-mediated N-methyl-d-aspartate (NMDA) channels allow intracellular Ca2+ overload. Insufficient ATP causes failure of energy-dependent Ca2+ pumps, and high [Na+]i prevents removal of Ca2+ by Na+/Ca2+ exchange pumps. γ-Aminobutyric acid (GABA) release can attenuate excitatory changes by opening a receptor-gated Cl−. C, Increased [Ca2+]i is amplified by calcium-induced release of Ca2+ from the endoplasmic reticulum (ER). Mitochondria may be injured attempting to buffer increasing [Ca2+]i, resulting in further metabolic failure and diminished ATP. Ca2+ activates nitric oxide synthase (NOS), transforming it to nitric oxide (NO), which is amplified by NO activation of NOS. NO contributes to the formation of damaging oxygen free radicals and inhibits mitochondrial cytochrome oxidase function. ATP degradation to xanthine and then uric acid by xanthine oxidase (XO) yields hydrogen peroxide (H2O2), which reacts with iron to form dangerous oxygen radicals. Oxygen free radicals react with lipids in the cell membrane, which leads to membrane degradation and more free radicals. Oxygen free radicals also can damage proteins.
Pharmacology, Devices, and Techniques

Cardiopulmonary Resuscitation

In the event of cardiac arrest, return of spontaneous circulation is the first priority in cerebral resuscitation. The degree of brain injury after cardiac arrest depends on the duration of complete cerebral ischemia (the downtime, or time before the initiation of cardiopulmonary resuscitation [CPR]) and duration of relative ischemia that occurs during CPR and that may occur from cardiogenic shock preceding or subsequent to the period of cardiac arrest. Events occurring after the restoration of flow (eg, transient hypoxia, hypotension) also can exacerbate brain damage in this dynamic and important early resuscitation time period. Extensive...
clinical evidence on hospital discharge rates and neurologic recovery rates supports the concept that success in resuscitation is inversely proportional to the duration of cardiac arrest. Although duration of arrest generally predicts outcome in the population of patients with sudden cardiac death, it cannot be used reliably to predict the outcome of individual patients. Modern brain resuscitation techniques focus on avoiding further secondary cerebral injury, which also affects outcome. Neurologic outcome of survivors is influenced by patient age, comorbidity and other individual characteristics.

The efficacy of closed chest CPR in generating adequate cerebral perfusion is somewhat controversial. Cardiac output during optimal standard closed chest CPR was previously estimated to be only 20% to 30% of normal, but more recent studies have suggested that higher cardiac outputs are possible in clinical practice and, unquestionably, effective CPR is essential to neurologic recovery after cardiac arrest.

Reperfusion

With cerebrovascular insults due to embolic or thrombotic mechanisms, randomized clinical trials have shown a benefit of revascularization in ischemic stroke. This is discussed in detail in Chapter 91.

Optimizing Perfusion and Oxygenation.

Maintaining cerebral oxygen delivery is a mainstay of therapy after ischemic brain injury. Oxygen delivery requires a sufficiently high CPP, sufficiently low cerebrovascular resistance (CVR), and adequate blood oxygen saturation.

Hypotension can dangerously lower cerebral blood flow (CBF) and is associated with worse outcome following cardiac arrest and traumatic brain injury (TBI). Normally, a change in systemic blood pressure triggers corresponding changes in CVR, mediated by cerebral arterial vasodilation or vasoconstriction. This capacity, termed cerebral autoregulation, functions to maintain a constant CBF over a wide range of arterial blood pressures. Autoregulation is often lost in the injured brain and, as a result, perfusion of ischemic tissue becomes passively dependent on CPP. Consequently, hypotension can compromise CBF and result in significant additional brain damage. Therefore, low arterial pressures should be rapidly normalized, with intravascular volume administration and vasopressors used as needed. In the absence of prospective clinical trial data to guide decision making, current recommendations for cardiac arrest patients are to maintain a MAP of 65 to 100 mm Hg. Induced hypertension, once believed to enhance CPP, is not currently a standard therapy due to concerns related to disruption of the blood-brain barrier and worsening of vasogenic edema.

Blood pressure goals fundamentally differ in intracerebral hemorrhage (ICH), in which elevated blood pressure at presentation is common due to a physiologic pressor response. Hypertension is a known risk factor for hematoma expansion, yet the targeted blood pressure goal in these patients remains controversial due to uncertainty regarding perfusion to the brain tissue surrounding the hematoma (ischemic penumbra). A large, multicenter, randomized controlled trial has demonstrated that rapid lowering of the systolic blood pressure (SBP) to less than 140 mm Hg is safe and may have a small but meaningful benefit on neurologic outcome. Consequently, we endorse immediate management with IV antihypertensives targeting an SBP less than 140 mm Hg. As in other conditions where there is a risk of secondary ischemic injury, hypertension should be diligently avoided by not allowing the MAP to drop below 65 mm Hg.

CVR is a critical determinant of CBF and may be affected by hyperventilation and microvascular patency. Although the cerebral circulation may lose its ability to adjust to blood pressure changes after ischemia, attenuated responsiveness to carbon dioxide and oxygen levels in arterial blood is generally present. Carbon dioxide is a potent vasoactive agent, and lowering the arterial carbon dioxide partial pressure (Paco2) by hyperventilation results in a rapid reduction of CBF of 2% for every 1-mm Hg decrease in the Paco2. Because reductions in CBF reduce total cerebral blood volume, hyperventilation quickly lowers ICP. Induced hyperventilation can transiently abort brainstem herniation in the presence of critically elevated ICP until an alternative therapy can be initiated. However, the vasocnstriction and increased CVR caused by hyperventilation can lead to dangerous reductions in CBF, with resulting cerebral ischemia. We recommend restricting the use of induced hyperventilation to the short-term treatment of immediately life-threatening cerebral herniation and severe intracranial hypertension that is not responsive to other measures, such as osmotic therapy. Chronic or prophylactic hyperventilation should not be used. Specific treatment for elevated ICP is described in the next section. In general, ventilation to maintain a Paco2 of 35 to 40 mm Hg is safe and appropriate, and inadvertent hyperventilation should be avoided.

Normal arterial oxygen saturation following resuscitation from ischemic brain injury is a primary goal. The injured brain may not be able to compensate for hypoxia by augmenting CBF, and cerebral oxygen delivery may diminish rapidly as the oxygen content of blood decreases. Hyperoxia secondary to the use of high concentrations of oxygen, however, has also been shown to increase oxidative brain injury in animal models of cardiac arrest and resuscitation and is associated with increased mortality in stroke patients’ and in post–cardiac arrest patients. Normoxia or mild hyperoxia (arterial partial pressure of oxygen, PaO2, of 80–120 mm Hg with oxyhemoglobin saturation percentage maintained in the high 90s) should be maintained through use of the lowest fraction of inspired oxygen (FIO2) possible. Because hypoxia, hypocapnia, and hypercapnia must be avoided, controlled ventilation is appropriate in the period after resuscitation, with sedation and muscle relaxation if needed. Continuous oximetry and capnography, correlated with intermittent arterial blood gas determinations, will provide the information necessary to optimize ventilation parameters.

Elevated Intracranial Pressure

The presence of intracranial hypertension is suggested by certain imaging findings and clinical features. Relevant computed tomography (CT) findings include compressed basal cisterns, diffuse sulcal effacement, and diffuse loss of differentiation between the gray and white matter, although ICP can be elevated without any of these findings. Suggestive clinical features include papilledema, bilateral sixth nerve palsy, and new third nerve palsy in a comatose patient. Definitive diagnosis requires invasive ICP monitoring placement. The decision to place an ICP monitor should be guided by neurosurgery whenever consultation is available. Most data on the management of elevated ICP is derived from literature on TBI, a condition in which ICP elevation commonly occurs. Although support from randomized controlled trials is lacking, the Brain Trauma Foundation has published guidelines for ICP monitor placement, which we recommend following in TBI patients whenever possible. These call for ICP monitor placement in all patients with an abnormal head CT scan and severe brain injury, defined as a Glasgow Coma Score of 3 to 8. ICP monitoring is considered appropriate in the presence of a normal head CT when two of the following are present: (1) age older than 40 years; (2) unilateral or bilateral motor posturing; and (3) SBP less than 90 mm Hg.

Guidelines are not available for ICP monitoring in other conditions involving ischemic brain injury, such as stroke, where it is...
generally not indicated. In particular, the clinical impact of intracranial hypertension due to anoxic brain injury following cardiac arrest is unclear and has not been studied in prospective trials. When cytotoxic edema severe enough to cause ICP elevation develops, it portends a very poor prognosis. Consequently, invasive ICP monitoring is not recommended in the management of global ischemic injury following cardiac arrest.¹

**Medical Treatment.** Medical treatment for elevated ICP has similarly not been proven effective in randomized controlled trials, and treatment protocols are primarily based on clinical experience and expert opinion. To ensure adequate cerebral perfusion, the MAP should be maintained above 65 mm Hg in all patients at risk for ICP elevation, and a CPP of 50 to 70 mm Hg should be targeted when ICP monitoring is available. Although the exact threshold for ICP treatment is unclear and may vary between individual patients, an ICP over 20 mm Hg has been associated with worse neurologic outcomes and should trigger treatment. Although there are many and somewhat diverse recommendations for the initial medical management of patients with elevated ICP, we suggest the following:

1. Position the patient with the head up by elevating the upper half of the bed or gurney to 30 degrees.
2. Maintain a neutral head and neck position to avoid jugular venous compression.
3. Treat fever. Administer antipyretic agents (eg, acetaminophen suppositories, 1000 mg every 6 hours) and use mist cooling as necessary; targeting a temperature at or below 37°C.
4. Minimize triggers of ICP increases.

This is accomplished by treating and avoiding pain. We recommend titrated doses of a hemodynamically stable opioid medication, such as fentanyl 25 to 50 µg every 5 minutes, as needed. Cough or bucking of the ventilator also should be avoided; this is best accomplished by achieving adequate sedation and analgesia to permit mechanical ventilation, as described in Chapters 1 and 2. Propofol is our sedative agent of choice for this purpose because it decreases cerebral metabolic activity and thereby CBF, and rapidly clears for neurologic assessment, as needed. Propofol can cause or contribute to hypotension, which generally is avoided by dosage adjustment.
5. Initiate osmolar therapy.

Osmolar therapy with mannitol or hypertonic saline can draw water across an intact blood-brain barrier and thereby lower ICP. Mannitol, 0.5 to 1 g/kg is given every 6 hours, up to a serum osmolality of 320 mOsm/kg. Treating with 30 mL of 23.4% normal saline appears to be at least as effective as mannitol at rapidly lowering ICP and reversing herniation, although a central line is necessary for safe administration; 30 to 60 mL can be given every 6 hours, up to a maximum serum sodium level of 160 meq/L. Because it is a potent diuretic, mannitol is preferred in cases of fluid overload, whereas hypertonic saline can be used as a resuscitative fluid.
6. Treat cases of refractory ICP elevation not amenable to the previous therapies.

Induced coma with a barbiturate will further decrease CBF and lower ICP. Pentobarbital is started with a 10-mg/kg loading dose over 1 hour, followed by a continuous infusion of 0.5 to 5 mg/ kg/h, titrated to achieve electroencephalographic burst suppression. Barbiturate administration is frequently accompanied by hypotension, which often requires vasopressors to maintain adequate CPP.
7. Mild induced hypothermia is an additional option in highly refractory cases.

Endovascular or surface cooling devices should be used to target a temperature of 32° to 36°C, titrated to achieve ICP control. Once cooled, rapid rewarming should be avoided because this may precipitate a significant ICP elevation.

**Surgical Treatment.** Surgical options for the management of refractory ICP include decompressive craniectomy and evacuation of intracranial hematoma, when present, and should be guided by neurosurgical consultation. In the event of severe cytotoxic edema following middle cerebral artery stroke, there is a benefit of early (<36 hours) decompressive hemicraniectomy in patients younger than 60 years. A bifrontal craniectomy is typically used to treat refractory ICP in TBI. Based on a recent randomized controlled trial that noted worse outcomes in TBI patients treated with very early craniectomy, we recommend reserving craniectomy for patients that have failed medical management, or as an urgent life-saving procedure when cerebral herniation is present in this population.⁶

**Maintenance of Body Temperature**

Hyperthermia (or fever) exacerbates brain injury and worsens neurologic outcome.⁷ Elevated body temperature increases cerebral metabolic demand by 8% to 13%/°C, escalates glutamate release, increases oxygen free radical production, and increases cytoskeletal and blood-brain barrier breakdown, with increased vasogenic edema. The core body temperature should be monitored in patients resuscitated from cerebral ischemia and measures should be initiated to prevent temperature increases in the postischemic period. In general, all temperature higher than 38°C should be treated aggressively with acetaminophen and surface cooling. Inducing therapeutic hypothermia has emerged as a therapy for comatose survivors of hypoxic-ischemic injury following cardiac arrest.

**Resuscitative Mild Hypothermia**

More than 50 years ago, hypothermia was first claimed to have a protective effect in global and focal brain ischemia. The neuroprotective mechanism is linked to a reduction of glutamate release, metabolic demand, free radical formation, and production of inflammatory cytokines. Cell signaling and genetic responses to cellular injury are also affected, and hypothermia may protect the brain from programmed neuronal cell death.

Mild hypothermia (32°–34°C) is easier to achieve and has fewer adverse effects than lower temperatures and has consistently been found to be neuroprotective in experimental models of cerebral ischemia. Two multicenter prospective, randomized controlled trials of mild hypothermia have shown marked improvements in neurologic outcome in comatose survivors of out-of-hospital cardiac arrest (Table 7.1).⁸⁻¹⁰ In these trials, the number needed to treat to have one additional patient with a good neurologic outcome was only about seven. Evidence-based guidelines recommend cooling unconscious adult patients after cardiac arrest to 33°C for 12 to 24 hours.¹¹ Recent investigations in adults and children have compared therapeutic hypothermia of 33°C to targeted temperature management” (TTM) of 36°C.¹² The safety and efficacy of TTM versus therapeutic hypothermia were no different. There is strong biologic evidence from earlier clinical trials and animal models that 33°C provides better neuroprotection. The TTM trial did not provide evidence that one target was easier or safer than the other. Most patients included in these trials had immediate bystander CPR and, by extension, were likely to have less severe neurologic insults than cardiac arrest patient resuscitated in routine practice outside Europe. Given the evolving nature of the evidence in this area, we recommend protocols that cool to a target of 33°C; however, practicing emergency clinicians should work with their intensive care colleagues to develop local protocols. A definitive temperature control device, surface or endovascular, with a feedback loop temperature sensor is required, regardless of the target chosen.
Cooling may begin during the out-of-hospital phase of resuscitation and may even be initiated before return of spontaneous circulation. Animal studies show that cooling should be initiated as early and rapidly as possible.

The optimal method of cooling patients resuscitated from cardiac arrest has not been established (see Chapter 8). Animal experimentation and consensus recommendations have suggested that cooling should be initiated as early and rapidly as possible. Cooling may begin during the out-of-hospital phase of resuscitation and may even be initiated before return of spontaneous circulation. In the positive clinical trials, hypothermia at $33 \pm 1 ^\circ C$ was achieved by 2 or 8 hours after return of spontaneous circulation and was maintained for 12 or 24 hours. Patients are allowed to rewarm passively or with a combination of passive and active rewarming. Rebound hyperthermia is common with passive rewarming and should be avoided.

Clinical trials of mild hypothermia in adults and children with traumatic brain injury have generally been small and have shown variable results, but large multicenter trials evaluating the use of mild hypothermia as a neuroprotectant or treatment for elevated ICP are ongoing. Therapeutic hypothermia following ischemic stroke is not of proven benefit, and we do not recommend its use (Box 7.1).

### Avoidance of Hyperglycemia

Postischemic hyperglycemia has detrimental effects on CBF, metabolism, edema formation, and neurologic outcome. Hyperglycemia after brain ischemia is strongly associated with worse outcomes in diabetics and nondiabetics. Because the brain is an obligate glucose consumer, brain resuscitation must balance hyperglycemia prevention with adequate cerebral glucose balance.

### Abbreviated Protocol for Induced Hypothermia After Cardiac Arrest

- Initiate definitive cooling by endovascular temperature control device at maximal rate to target temperature of $33 ^\circ C$.
- Prevent shivering with sedation and nondepolarizing paralytic—bolus in the ED, bolus or drip in the ICU.
- Avoid hypotension and hypoxia.
- Most ED diagnostic evaluation, if needed, should follow initiation of cooling. In patients with acute myocardial infarction (MI) who are going to primary coronary intervention, cooling should not delay door to balloon time. Cooling is initiated in the ED if there is time before the catheterization laboratory is ready; otherwise, cooling is initiated in the laboratory.
- Admit to ICU.
- Continuous electroencephalographic monitoring for occult status epilepticus recommended. Treat seizures if present.
- Manage arterial blood gases in a consistent manner (may choose pH stat or alpha stat).
- At 24 hours after initiation of cooling, initiate rewarming to a target temperature of $36.5 ^\circ C$ at a rate of 0.15%/h.
- Discontinue paralysis at the onset of warming. Control shivering with sedation, narcotics, and surface counterwarming.
- Lighten sedation as tolerated as rewarming progresses.
- Discontinue endovascular temperature control device after 48 hours (may use the device to maintain normothermia after rewarming is complete until it is removed).
- Remove or minimize sedation to allow neurologic evaluation before 72 hours to allow the best possible clinical prognostication at that time point; neurology consultation recommended.

*Modified from University of Michigan protocol.
availability. Cerebral microdialysis studies in humans have shown that tight glucose control (<120 mg/dL) is associated with low cerebral glucose and elevated lactate levels, which in turn are associated with increased mortality. Current recommendations for glucose control following cardiac arrest are to avoid hypoglycemia and target a blood glucose level of less than 180 mg/dL. This can typically be achieved by the administration of subcutaneous insulin, although a continuous intravenous insulin infusion is sometimes necessary. A multicenter clinical trial of intensive insulin therapy in acute ischemic stroke is currently underway.

**Seizure Management**

Although the prevention of seizures has not been demonstrated to improve neurologic recovery, seizures are clearly not desirable in the postischemic period. Seizures can result from global cerebral ischemia and may exacerbate underlying brain injury. Seizure activity can increase brain metabolism by 300% to 400%, worsening the mismatch between oxygen delivery and demand, with greater metabolic failure and neuronal loss and worsened neurologic outcome. When present, prolonged seizures or status epilepticus following cardiac arrest are strongly, although not invariably, associated with a poor neurologic outcome. Nonconvulsive status epilepticus has been reported after cardiac arrest; consequently, continuous electroencephalographic monitoring is frequently used in coma survivors, and we recommend its use for patients who are paralyzed while receiving therapeutic hypothermia. Electroencephalographic findings have been shown to predict neurologic outcome after cardiac arrest reliably and, in the future, electroencephalographic monitoring may be a core component in prognostication algorithms.

We do not recommend the prophylactic use of anticonvulsant drugs in patients resuscitated from cardiac arrest, but seizures should be quickly and effectively treated. Lorazepam, 0.1 mg/kg, with a maximum rate of 2 mg/min, is the preferred first-line agent to abort seizures and should be followed by longer term treatment with an antiepileptic drug. Phenytoin, levetiracetam, or valproic acid are equally efficacious options based on current data. These are all available in IV formulations. Treatment is initiated with identical 20-mg/kg loading doses. In intracerebral hemorrhage, the prophylactic use of anticonvulsants has been associated with worse neurologic outcomes, and we concur with current guidelines that do not recommend their routine use. In TBI, prophylaxis with phenytoin reduces seizures during the first 7 days, but not beyond, and has not been shown to improve outcome. There are limited data suggesting that prophylaxis with levetiracetam may be better tolerated than phenytoin, so 7 days of levetiracetam, 500 mg bid, is our preferred regimen for prophylaxis in TBI patients.

**OUTCOMES**

Cerebral ischemia is a frequently fatal and highly morbid condition, but the prognosis for its victims is not universally poor. An increasing body of data is providing more complete and precise estimates of the functional outcomes and quality of life of survivors, and the results are better than many emergency clinicians assume.

However, identification of reliable prognostic indicators of severe brain injury is hampered by the self-fulfilling prophecy, in which counseling provided to families of patients with a presumed poor prognosis leads to withdrawal of life-sustaining treatments, thereby seeming to confirm the poor prognosis. There is significant individual and institutional variation in the implementation of “Do not resuscitate” (DNR) orders and early withdrawal of life support, and these variations can profoundly affect our understanding of outcomes. In an important study using a large data set of patients with ICH, institution of DNR orders within 24 hours was strongly associated with mortality, independently of other known risk factors. Consequently, recent ICH guidelines have emphasized the importance of avoiding assigning new DNR status within the first day of hospital presentation. Prognostication in TBI, which disproportionately affects young adults, can be particularly difficult, and there are examples of good outcomes in spite of a prolonged hospital course and numerous poor prognostic indicators.

On the other hand, prolonged survival with significant disability also may be a tragic outcome, and consideration of this may lead emergency clinicians and families to consider withdrawal of life support. This may account, in part, for the nihilism common among emergency clinicians treating patients with cardiac arrest. This may arise in part from the fact that most survivors of cardiac arrest are comatose at the time of admission and without early prognostic findings suggesting which patients will have a favorable outcome. The most recent American Academy of Neurology (AAN) guidelines (2006) for prognostication after cardiac arrest are driven by data from the pretherapeutic hypothermia era. These guidelines identified six factors that reliably predict poor outcome—absent pupillary response, corneal reflex, or motor response at 72 hours; neuron-specific enolase (NSE) level higher than 33 µg/L; myoclonic status epilepticus within 24 hours; and bilateral, absent, somatosensory evoked potentials. More recent data from patients undergoing therapeutic mild hypothermia have cast doubt on the reliability of several of these factors. In particular, NSE levels and motor responses at 72 hours have had poor predictive value in these patients. Additionally, a higher false-positive rate has been associated with absent corneal reflexes at 72 hours and early myoclonic status epilepticus. Further clinical studies and meta-analyses are needed to clarify reliable prognostic indicators.

Despite continued work to identify an imaging biomarker for outcome after cardiac arrest, there is no established role for early magnetic resonance imaging or CT in prognostication in survivors of cardiac arrest. In the near future, serum biomarkers of brain injury may identify the potential for neurologic recovery early in a patient’s course and help guide therapy. Until early predictions of outcome can be made accurately, the emergency clinician should consider most survivors of cardiac arrest as having a significant chance of full recovery (14%–55%); however, patients with severe coma (motor plus brainstem four score below 4 in the absence of sedatives and paralytics) within 6 hours of resuscitation have a lower likelihood of recovery (5%–10%).

**SUMMARY**

Rapidly expanding knowledge about the pathophysiology of postischemic brain injury has stimulated the search for effective cerebral resuscitation therapies. Newly proven therapies such as resuscitative hypothermia will continue to be studied and will improve the outcomes of patients with ischemic brain injury in future years. Although experimental work has suggested many potentially promising brain resuscitation therapies, attention should also be paid to determining the benefits of existing standard therapies. Because of the complexity and interconnectedness of the pathophysiologic cascades that occur after cerebral ischemia, it is likely that a multifaceted therapeutic approach targeting mediators of secondary brain injury, rather than a single pharmacologic agent, is needed to reduce neurologic damage after cardiac arrest.

It is crucial that the emergency clinician recognize that the patient resuscitated from ischemic injury is, contrary to his or her outward appearance, in a dynamic stage of brain injury. At present, patients should be protected from further brain injury caused by hypotension, hypoperfusion, ICP elevation, hypoxia,
hyperthermia, hypoglycemia, hyperglycemia, and seizures. Coma
tose survivors of out-of-hospital cardiac arrest should now
also undergo resuscitative hypothermia or targeted temperature
management. In the future, cerebral resuscitation may also involve
other specific pharmacologic interventions to derail the process
whereby brain cells slowly die after ischemic brain injury.

**KEY CONCEPTS**

- Neuronal injury is a dynamic process that continues for hours or days
  after an ischemic insult to the brain.
- Hypotension and hypoperfusion should be avoided by maintaining
  MAP > 65 mm Hg and CPP of 50–70 mm Hg.
- Normoxia or mild hyperoxia, with PaO₂ of 80–120 mm Hg and
  oxyhemoglobin saturations in the high 90s, should be
  maintained. Hypoxia and significant hyperoxia should be avoided.
- ICP elevation can further exacerbate ischemic brain injury. Initial
  management should include optimizing patient positioning while
  providing adequate analgesia and sedation. Management should
  then be escalated in a stepwise fashion to include hypertonic
  therapy, deep sedation with barbiturates, hypothermia, and
  surgery as needed.
- Hyperventilation decreases cerebral blood flow and should be
  avoided by targeting a PaCO₂ of 35–40 mm Hg. In the event of
  life-threatening cerebral herniation or significant ICP elevation,
  therapeutic hyperventilation is appropriate only as a short-term
  intervention bridging to more definitive therapy (ie, craniectomy).
- Hyperglycemia worsens neurologic outcome. Subcutaneous or IV
  insulin should be used to maintain a glucose level <180 mg/dL.
- When present, seizures should be promptly aborted using IV
  lorazepam, followed by treatment with IV phenytoin, valproic
  acid, or levetiracetam, with an initial 20-mg/kg loading dose. The
  prophylactic administration of antiepileptic drugs is not
  recommended, except for 7 days immediately following TBI.
  Levetiracetam, 500 mg bid, is a preferred agent.
- Fever is an important mediator of secondary brain injury and all
  temperatures >38°C should be treated promptly with
  acetaminophen and surface cooling.
- Comatose survivors of out-of-hospital cardiac arrest should be rapidly
  cooled in the ED, maintained at a constant target of 33°–36°C in an
  ICU setting for 24 hours after resuscitation, and receive targeted
  temperature management to prevent hyperthermia after this period.

CHAPTER 7: QUESTIONS AND ANSWERS

7.1. To maximize cerebral blood flow, a patient with a normal intracranial pressure who is undergoing resuscitation should be ventilated to maintain a partial pressure of carbon dioxide (Paco2) within what range?

A. 20 to 25 mm Hg
B. 25 to 30 mm Hg
C. 30 to 35 mm Hg
D. 35 to 40 mm Hg
E. 40 to 45 mm Hg

Answer: D. Carbon dioxide is a potent vasoactive agent, and lowering of the Paco2 by hyperventilation results in rapid reduction of cerebral blood flow (CBF). Because reductions in CBF reduce total cerebral blood volume, hyperventilation may transiently abort brainstem herniation in the presence of critically elevated intracranial pressure (ICP) until osmotherapy or ventriculostomy can be initiated. When ICP is not elevated, however, the vasosonction and increased cerebrovascular resistance (CVR) caused by hyperventilation can cause potentially dangerous reductions in CBF. In general, ventilation to maintain a Paco2 between 35 and 40 mm Hg is safe and appropriate.

7.2. True or false? Induced hypothermia for comatose survivors of ventricular fibrillation is a class 1A recommendation in the 2010 American Heart Association/Committee Guidelines.

Answer: True.

7.3. Select the best answer. Which of the following statements is false?

A. Early magnetic resonance imaging (MRI) and serum biomarkers have a clearly established role in determining the prognosis of patients within 48 hours after cardiac arrest.
B. In a study from the Resuscitation Outcomes Consortium, median survival to hospital discharge among all patients with emergency medical services (EMS) responses for cardiac arrest was 8.4%.
C. In cardiac arrest patients who survive to hospital admission, 14% to 55% have good long-term outcomes.
D. The vast majority of 1-year survivors of cardiac arrest are neurologically intact.

Answer: Statement A is false. The role of early imaging, neurophysiologic testing, and serum biomarkers in predicting outcome has not yet been clearly established at any time point, especially not within 48 hours.

7.4. True or false? A patient with return of spontaneous circulation after 15 minutes of cardiac arrest has likely already suffered substantial neuronal cell death.

Answer: False. Although a cascade of cellular pathways will have been triggered, the resulting neuronal cell death is usually delayed by hours or days.

7.5. Select the best answer. Which of the following is associated with worse neurologic outcomes in comatose survivors of cardiac arrest?

A. All of these
B. Hypothermia
C. Hypotension
D. Hypoxia
E. Only hypotension and hyperthermia

Answer: Statement A is the best answer. Hypothermia, hypoxia, and hyperthermia (as well as hyperglycemia and seizures) are all associated with worse neurologic outcomes in comatose survivors of cardiac arrest.
CHAPTER 8

Adult Resuscitation

Michael C. Kurz | Robert W. Neumar

PRINCIPLES

Background

It is estimated that out-of-hospital cardiac arrest affects approximately 326,000 patients each year in the United States (an estimated annual incidence of 100/100,000). Of these, approximately 176,000 are treated by emergency medical services (EMS). Most EMS-treated, out-of-hospital cardiac arrests occur at home (70%) and are unwitnessed (50%). The proportion of EMS-treated cardiac arrest patients with an initial rhythm of ventricular fibrillation (VF) has declined over time to approximately 20%. Furthermore, the number of patients receiving bystander cardiopulmonary resuscitation (CPR) remains low, averaging 45%. Bystander automated external defibrillators (AEDs) are applied in only 1% of home arrests and 8% of arrests in public settings.

The most recent epidemiologic data from cardiac arrest registries have indicated that the survival rate of hospital discharge for EMS-treated, out-of-hospital cardiac arrest is about 11%. However, tremendous regional variability in survival to hospital discharge after EMS-treated cardiac arrest has been reported, ranging from 3% to 17%. For the subset of patients who achieve return of spontaneous circulation (ROSC) long enough to be admitted to the hospital, there is significant interinstitutional variability in survival, ranging from 19% to 59%. Of patients surviving to hospital discharge, independent of neurologic status on presentation, 78% have good neurologic function (cerebral performance category of 1 or 2). For comatose postcardiac arrest patients meeting study inclusion criteria for hypothermia-targeted temperature management (TTM), the reported survival rate with good neurologic function is approximately 50%. The entire system of care affects patient outcomes, and the variability in outcomes across the country likely reflects local and regional variability in how well these systems function.

Anatomy, Physiology, and Pathophysiology

Understanding the underlying causes of cardiac arrest helps direct therapy and diagnostic testing during resuscitation and in the immediate post–cardiac arrest period (Table 8.1). Cardiac arrest caused by VF or pulseless ventricular tachycardia (pVT) usually has a primary cardiac origin. Coronary artery disease is a common pathologic condition found in patients who experience out-of-hospital cardiac arrest, and multiple observational studies have demonstrated disease rates comparable to those of patients undergoing clinically indicated coronary angiography. Less common are inherited syndromes associated with sudden cardiac death due to ventricular dysrhythmias, including hypertrophic cardiomyopathy, Brugada’s syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia, and arrhythmogenic right ventricular cardiomyopathy. Pulseless electrical activity (PEA) and asystole may also occur as presenting rhythms in patients with a cardiac cause of arrest. These rhythms can occur in response to respiratory insufficiency secondary to cardiac dysfunction or to deterioration of VF or pVT when cardiac arrest is prolonged, or they may develop in response to resuscitation treatments such as defibrillation.

Primary respiratory failure generally causes initial hypertension and tachycardia, followed by hypotension and bradycardia and progressing to PEA, VF, or asystole. Circulatory obstruction (eg, tension pneumothorax, pericardial tamponade) and hypovolemia generally manifest with initial tachycardia and hypotension, progressing through bradycardia to PEA, but also may deteriorate to VF or asystole.

Other less common causes for cardiac arrest include electrolyte disturbances, drug toxicity, and electrocution. The most common metabolic cause of cardiac arrest is hyperkalemia, which is usually seen in patients with renal failure. Hyperkalemia results in progressive widening of the QRS complex, which can deteriorate to pVT, VF, asystole, or PEA. Other electrolyte abnormalities (eg, hypomagnesemia, hypermagnesemia, hypokalemia) may lead to significant dysrhythmias, but the frequency with which they cause cardiac arrest has not been documented and is likely very low. Cardiac arrest from drug toxicity has specific characteristics, depending on the presenting toxidrome. Specific therapy directed at drug toxicity is essential but may not be immediately effective, and prolonged resuscitation efforts involving a method that provides adequate perfusion may be needed. Electrocautery causes cardiac arrest through primary dysrhythmias or apnea. Alternating current in the range of 100 mA to 1 A (household and light industry) generally causes VF, whereas currents greater than 10 A (heavy industry or electrical transmission infrastructure) can cause ventricular asystole. Lightning produces a massive direct current electrocution that can result in asystole and prolonged apnea (see Chapter 134).

Hypothermia-induced cardiac arrest can manifest with any electrocardiographic rhythm, and successful resuscitation depends on rapid rewarming, which often requires invasive measures (eg, intravascular rewarming, peritoneal or thoracic lavage, or venous-arterial extracorporeal membrane oxygenation [VA-ECMO]; see Chapter 132). Once circulation is restored, patients should be warmed to 32° to 34°C (90°–93°F) for patients without contraindications to targeted temperature management following cardiac arrest. Drowning is a form of asphyxia usually resulting in bradyasystolic arrest. Because drowning often is accompanied by hypothermia, the victim may benefit from prolonged resuscitation efforts, similar to resuscitation efforts for hypothermia.

MANAGEMENT

Decision Making

Most cardiac arrest cases managed in the emergency department (ED) initially occur outside the hospital. An increasing number of first responders, nontraditional providers (eg, teachers, flight attendants), and public venues (eg, airports, casinos, sports arenas, schools) are being equipped with AEDs. When coupled with regional and statewide campaigns to improve bystander CPR rates, including hands-only and dispatcher-assisted CPR, dramatic resuscitation rates have been achieved in communities.

CNS, Central nervous system; COPD, chronic obstructive pulmonary disease.

where lay public providers feel empowered to respond within the first few minutes of arrest. Programs that fail to improve rates of bystander CPR or AED use within this critical time window are unlikely to achieve increased survival rates.

Advanced life support) units staffed by paramedics often have standing orders to follow advanced cardiac resuscitation protocols. In cases of cardiac arrest refractory to properly performed advanced prehospital measures, the patient may be pronounced dead at the scene if appropriate protocols have been outlined within the system. However, if advanced hospital-based resuscitation strategies such as extracorporeal cardiopulmonary resuscitation (ECPR) and percutaneous coronary intervention (PCI) are available during mechanical CPR, then transport to a comprehensive resuscitation center may still be warranted. In systems where patients are transported in cardiac arrest, mechanical CPR has the potential to result in better quality chest compression during transport and is likely to be safer for EMS providers.

In the ED, the management of cardiac arrest occurs in an orchestrated effort by a health care team led by an emergency clinician who can monitor the efficacy and response to therapeutic interventions. It is often difficult to determine the cause of cardiac arrest at presentation. Although a differential diagnosis can be formulated based on history, physical examination, and electrocardiographic rhythm on arrival, key information often is not available or is unreliable. The differential diagnosis potentially can be narrowed by the patient’s age, underlying diseases, and medications, when known.

History and Physical Examination

Historical information from the family, bystanders, and EMS personnel provides key information regarding cause and prognosis. Information surrounding the event includes whether the arrest was witnessed, time of arrest, what the patient was doing (eg, eating, exercising, trauma), possibility of drug ingestion, time of initial CPR, initial electrocardiographic rhythm, and interventions by EMS providers. Important past medical history includes baseline health, previous heart, lung, or renal disease, malignancy, hemorrhage, and infection, and risk factors for coronary artery disease and pulmonary embolism. The patient’s current medications and allergies also should be obtained, if possible.

Physical examination of a cardiac arrest patient is necessarily focused on a few key goals: (1) ensuring the adequacy of airway maintenance and ventilation; (2) confirming the diagnosis of cardiac arrest; (3) finding evidence of the cause; and (4) monitoring for complications of therapeutic interventions. This examination occurs in descending order of importance, simultaneously with therapeutic interventions, and is repeated frequently to assess for response to therapy and occurrence of complications (Table 8.2).

Cardiopulmonary arrest is defined by the triad of unconsciousness, apnea, and pulselessness. The pulse is palpated in a large artery (carotid or femoral). If any question exists about the diagnosis of pulselessness, CPR should be initiated. With sudden onset of cardiac arrest, as in VF, loss of consciousness occurs within 15 seconds, although agonal gasping respirations may persist for several minutes. Primary respiratory arrest results in transient tachycardia and hypertension due to mounting hypoxia, loss of consciousness, bradycardia, and pulselessness.

After the initial minutes of cardiac arrest, the physical examination may provide little evidence of the duration of arrest. Pupils dilate within 1 minute but constrict if CPR is initiated immediately and performed effectively. Dependent lividity and rigor mortis develop after hours of cardiac arrest. Temperature is an unreliable predictor of duration of cardiac arrest because it does not decrease significantly during the first hours of arrest. Moderate to severe hypothermia may cause cardiac arrest or be caused by prolonged arrest.

Monitoring

Traditional monitoring during CPR has relied on evaluation of the electrocardiogram (ECG) in one or more leads and palpation of carotid or femoral artery pulses. Although the lack of a palpable pulse during CPR may indicate inadequate forward flow, the degree of forward flow cannot be estimated accurately in the presence of a palpable pulse because pressures generated during CPR may be transmitted equally to the venous and arterial vasculatures. In addition, myocardial blood flow does not depend on the palpated arterial pressure during chest compression (CPR systole), but rather on the difference between aortic and right atrial pressures during relaxation (CPR diastole), which is defined
as the coronary perfusion pressure (CPP). Electrocardiographic monitoring during cardiac arrest indicates the presence or absence of electrical but not mechanical activity. Although these two monitoring modalities may be the best attainable in certain circumstances, they do not provide reliable information regarding the effectiveness of CPR and interventions or prognosis.

Unfortunately, no ideal monitoring technique provides all the information that might be desired during resuscitation, and the modalities discussed below can be challenging to initiate during CPR. A brief overview is provided of CPP, end-tidal carbon dioxide (ETCO₂), and central venous oxygen saturation (ScvO₂) monitoring, which, if available, can be used to detect inadequate CPR with high specificity (Table 8.3). In addition, several of these techniques are useful in the immediate post–cardiac arrest period.

Arterial Blood Pressure and Coronary Perfusion Pressure
Successful resuscitation of the arrested heart depends on generating adequate CPP during CPR, which has been directly correlated with myocardial blood flow. Animal and human studies have indicated that a minimum CPP of 15 mm Hg is necessary to achieve ROSC if initial defibrillation attempts have failed. Unfortunately, CPP monitoring is rarely feasible in ED resuscitations of cardiac arrest patients because it requires an indwelling arterial pressure catheter and central venous catheter, both transduced properly to provide simultaneous readings.

Invasive arterial blood pressure monitoring alone can be helpful in guiding resuscitation and should be used when an indwelling arterial pressure catheter is already in place. When adequate personnel are available, it is often feasible to cannulate the femoral artery during CPR, especially with ultrasound guidance. Human studies have shown that radial or femoral arterial relaxation pressures reliably reflect aortic relaxation pressures during CPR. In one ED-based study, all patients who achieved ROSC had arterial relaxation pressure during CPR that reached or exceeded 17 mm Hg. Titrating resuscitation efforts to arterial relaxation (diastolic) pressure is less reliable than CPP because improper CPR (eg, leaning on chest during CPR diastole and...

CPP, Coronary perfusion pressure; PETCO₂, partial pressure of CO₂ in exhaled air at the end of expiration; ScvO₂, central venous oxygen saturation.

End-Tidal Carbon Dioxide

The partial pressure of CO₂ in exhaled air at the end of expiration (PETCO₂) can be a reliable indicator of cardiac output during CPR. This is most reliably measured through waveform capnography after endotracheal intubation. PETCO₂ depends on CO₂ production, alveolar ventilation, and pulmonary blood flow (ie, cardiac output) and correlates well with CPP and cerebral perfusion pressure during CPR. Therefore, when minute ventilation is held constant (a desirable but often unmet goal) and no exogenous CO₂ is introduced (eg, with sodium bicarbonate [NaHCO₃] administration), only increased cardiac output during CPR and ROSC significantly increase PETCO₂. Resuscitation after cardiac arrest is likely to fail if PETCO₂ values of 10 mm Hg or more are not achieved. Therefore, values less than 10 mm Hg should prompt the clinician to enhance the quality of CPR, improving compression rate, depth, or recall.

PETCO₂ monitoring also can aid in the diagnosis and treatment of PEA. Patients in a state of PEA with mechanical heart activity may have pulsatile flow that simply cannot be detected by palpation of a pulse. In such cases, PETCO₂ levels may be elevated, even without compressions. Use of cardiac ultrasound in such cases can identify corresponding cardiac activity. In these cases, volume expansion or the use of vasopressors and inotropes is indicated. PETCO₂ monitoring also is useful in rapidly detecting the success of tension pneumothorax decompression, pericardiocentesis for pericardial tamponade, and fluid resuscitation for hypovolemia. ROSC causes immediate and significant increases in PETCO₂. Therefore, PETCO₂ monitoring can detect ROSC at any time during the chest compression cycle, providing valuable guidance for pharmacologic therapy and minimizing the need for a pulse check when organized rhythms are detected (Fig. 8.1).

Finally, PETCO₂ monitoring is valuable in patients after ROSC to monitor endotracheal tube placement (waveform capnography recommended), titrate minute ventilation to avoid hyperventilation, and detect sudden hemodynamic deterioration.

Central Venous Oxygen Saturation

Central venous oxygen saturation, ScvO₂, when available, provides an additional method to monitor the adequacy of resuscitative measures. The mixed venous blood oxygen saturation in the pulmonary artery (SvO₂) represents the oxygen remaining in the blood after systemic extraction. Studies have shown a close correlation between ScvO₂ and SvO₂ during CPR. Because oxygen consumption remains relatively constant during CPR, as does arterial oxygen saturation (SaO₂) and hemoglobin, changes in ScvO₂ reflect changes in oxygen delivery by means of changes in cardiac output.

Although used most commonly in the intensive care unit (ICU) setting, multilumen oximetric ScvO₂ catheters are placed in the same manner as regular central venous catheters and can be used to monitor ScvO₂ continuously in real time. ScvO₂ values normally range from 60% to 80%. During cardiac arrest and CPR, these values range from 25% to 35%, indicating greatly enhanced oxygen extraction of tissues owing to the inadequacy of oxygen delivery during CPR. Failure to achieve an ScvO₂ of 40% or greater during CPR has had a negative predictive value for ROSC of almost 100%. ScvO₂ also helps to detect ROSC rapidly without interruption of chest compressions, because ROSC will result in a rapid increase in ScvO₂ as oxygen delivery to tissues dramatically increases. ScvO₂ monitoring is also useful in the post–cardiac arrest period for hemodynamic optimization and for recognition of any sudden deterioration in the patient’s clinical condition.

Pharmacologic Therapy

Pharmacologic therapy during CPR improves the proportion of patients who achieve ROSC. However, there is yet to be a randomized prospective placebo-controlled clinical trial that has been adequately powered to determine if pharmacologic therapy during CPR improves long-term survival or neurologic outcome. Therefore, the primary focus of advanced life support remains early defibrillation and high-quality CPR, guided by physiologic monitoring.

For ongoing resuscitation of arrest rhythms that fail to respond to CPR and defibrillation, intravenous (IV) or intraosseous (IO) access should be obtained so that vasopressor therapy (typically, epinephrine 1.0 mg, IV or IO) can be administered and repeated every 3 to 5 minutes. Simultaneous administration of epinephrine and vasopressin does not improve the outcome relative to epinephrine alone, regardless of presenting rhythm. When intravascular pressure monitoring is available, it is reasonable to titrate vasopressor therapy during CPR to achieve a CPP of more than 15 mm Hg or arterial relaxation pressure more than 20 to 25 mm Hg.

For refractory VF or pVT, antidysrhythmics can be administered up to their maximum loading dose. Amiodarone (300 mg IV) is the only antidysrhythmic agent that has been shown to improve the rate of VF conversion to a perfusing rhythm.

Other medications that may be of value in special cases include magnesium sulfate in torsades de pointes and hypomagnesemia, calcium chloride in hyperkalemia, NaHCO₃ in tricyclic antidepressant overdose, and 50% dextrose in water in documented hypoglycemia. Routine administration of atropine outside the setting of bradycardia is not beneficial.

Devices and Techniques

Echocardiography

The main usefulness of echocardiography is diagnostic, especially in patients with PEA. Echocardiography distinguishes organized pulseless cardiac activity that does or does not result in mechanical
Adult Resuscitation

of CPR, a single measurement may not be as useful as continuous, oximetric ScvO2 monitoring.

Other laboratory studies during CPR are typically not available in time to guide therapy, but may serve to confirm a diagnosis following successful resuscitation. Serum electrolyte levels may be ordered to rule out hyperkalemia, hypokalemia, hypomagnesemia, hypercalcemia, and hypocalcemia; however, empirical therapy should be initiated immediately if a high clinical suspicion exists.

Hemoglobin levels may indicate hemorrhage, but the initial hemoglobin value may be normal, even in acute exsanguinating hemorrhage, owing to a lack of rapid vascular and interstitial compartment equilibration.

Resuscitation

Restoration of adequate cardiac function is the defining factor of ROSC, but restoration of good neurologic function is the defining
factor of successful resuscitation. The likelihood of achieving both these goals decreases with every minute that the patient remains in cardiac arrest. Although many interventions are specific to the presenting electrocardiographic rhythm, most therapeutic modalities and monitoring techniques are used in all rhythms, making separate algorithms redundant.

Interventions should be performed rapidly and efficiently to maximize the chances of a good neurologic outcome. The quality of CPR is perhaps the most underappreciated component of the resuscitation effort. Important quality performance measures include compression rate (100–120 compressions/min), compression depth (5–6 cm), chest compression fraction (ie, CPR performed 80 out of every 100 seconds of the pulseless interval), full chest recoil (no residual leaning between compressions), and ventilation rate (10 breaths ventilations/min). Furthermore, hyperventilation has been shown to be common, and more than 10 ventilations/min are unnecessary and reduce cardiac output during CPR. A 30:2 compression-to-ventilation ratio is currently recommended for health care professionals in all adult resuscitation scenarios until an advanced airway has been established. Once an advanced airway is secured, CPR should be performed continuously, without pausing for ventilation, while providing one ventilation every 6 seconds (10 ventilations/min). As indicated earlier, if PETCO2 is to be helpful as an indicator of cardiac output during CPR, minute ventilation should be relatively constant. Although recent evidence has suggested that chest compression–only CPR is no less effective than traditional CPR when performed by bystanders in the out-of-hospital setting, trained providers who are willing and able to provide ventilations should do so. Although oxygen uptake from the lungs is low during CPR, oxygen remaining in the functional residual capacity of the lung will be continuously consumed as CPR progresses, if not replenished. The exception to this is when inadequate personnel are present to provide compressions, ventilation, and other resuscitative measures. Intubation should be performed only when capable personnel are available and without interruption of chest compressions. Use of supraglottic airway adjuncts may be beneficial alternatives for airway management in the out-of-hospital phase of resuscitation to minimize interruptions to chest compressions.

In addition to monitoring specific CPR performance parameters, physiologic monitoring, if available, can help optimize CPR quality for the individual patient (see Table 8.3). If the inadequacy of CPR is recognized early in the resuscitation despite optimized therapy, the physician in charge may consider more invasive measures such as ECPR or coronary angiography and PCI with ongoing chest compressions if these modalities are readily available and there is significant potential for survival with good neurologic function. After prolonged arrest, however, clear indications that CPR is inadequate (based on appropriate monitoring techniques) can be a contributing factor in the decision to cease resuscitation efforts. Fig. 8.2 depicts an algorithm for the management of cardiac arrest. Interventions specific to each rhythm are discussed in the following sections.

**Defibrillation**

VF and pVT are treated identically because they are generally caused by the same mechanisms and respond to the same interventions. Traditional monophasic defibrillators have almost completely been replaced by defibrillators using biphasic waveforms. With biphasic defibrillation, the energy required for successful defibrillation, the so-called defibrillation threshold, is lower than with monophasic defibrillation. The biphasic waveform increases the likelihood of initial defibrillation success and decreases the likelihood of post–countershock myocardial dysfunction. Despite documented advantages of lower defibrillation threshold and reduced myocardial injury with the use of biphasic defibrillation, data are currently inadequate to conclude that any specific waveform (biphasic or monophasic) is superior to any other in achieving ROSC or survival to hospital discharge. New defibrillation technologies have stimulated a reevaluation of optimal defibrillation strategies. Current consensus suggests that the most effective strategy is delivery of single countershocks at optimal energy levels, with minimal pauses in CPR. This is facilitated by the placement of defibrillation paddles early in the resuscitation sequence, thus not requiring a pause while defibrillation paddles and conducting gel are placed for each shock. Health professionals should use the manufacturer-recommended countershock energies for biphasic defibrillators because these range from 120 to 360 J and are device-specific.

**Pulseless Electrical Activity**

PEA is defined as coordinated electrical activity of the heart (other than VT or VF) without a palpable pulse. This group of dysrhythmias includes electromechanical dissociation (EMD), in which no myocardial contractions occur, and pseudo-EMD, in which myocardial contractions occur but are inadequate, and no pulse can be palpated. Although distinguishing EMD from pseudo-EMD may be useful in determining cause and guiding treatment, in most cases of primary PEA there is a natural progression from hypotension to pseudo-EMD to EMD.

True EMD is the result of a primary disorder of electromechanical coupling in myocardial cells. It often is associated with abnormal automaticity and conduction, resulting in bradycardia and a wide QRS complex. Although the mechanism of uncoupling is unclear, it usually is associated with global myocardial energy depletion and acidosis resulting from ischemia or hypoxia. True EMD typically occurs after defibrillation following prolonged VF and is associated with hyperkalemia, hypothermia, and drug overdose.

Pseudo-EMD caused by global myocardial dysfunction is a transient state in the progression to EMD and has the same cause. An additional cardiac cause of pseudo-EMD is papillary muscle and myocardial wall rupture, in which the ventricle continues to contract but forward flow is greatly diminished. Pseudo-EMD also

### Therapy

| END resuscitative efforts when cardiopulmonary arrest is refractory to optimized therapy and reversible causes have been corrected. |

---

**Fig. 8.2.** Emergency treatment algorithm for treatment of cardiac arrest. *If arrest is witnessed and known to be of short duration, immediate rhythm assessment and defibrillation or ventricular fibrillation/ventricular tachycardia (VF/VT) precede cardiopulmonary resuscitation (CPR).* Biphasic defibrillation should use manufacturer-recommended energy versus monophasic defibrillation (360 J). *See Table 8.4. Endotracheal intubation or supraglottic airway, when feasible, with minimal interruption in chest compressions.* Epinephrine, initial dose of 1 mg IV or IO. Repeat every 3 to 5 minutes. Subsequent doses may be increased up to 0.1 mg/kg. An alternative to epinephrine is vasopressin, 40 U, via IV push. The dose (40 U) can be repeated once in 3 minutes, followed by the administration of epinephrine every 3 to 5 minutes. Amiodarone, 300 mg IV push, followed by 150 mg every 30 minutes. Lidocaine is an alternative antidysrhythmic if amiodarone is not available; magnesium sulfate, 1 to 2 g IV push in torsades de pointes or known hypomagnesemia, may be given. Changes in the partial pressure of end-tidal carbon dioxide (PETCO2) may not be predictive of myocardial blood flow in the setting of high-dose vasopressor therapy. Invasive monitoring should be performed only if adequate personnel are available and if it would not delay therapeutic interventions. AoDP: Aortic diastolic pressure, ECG, electrocardiogram; EMD, electromechanical dissociation; PEA, pulseless electrical activity; ScvO2, central venous oxygen saturation.

---

...continued from previous page...

...may be caused by primary supraventricular tachycardia. Additional extracardiac causes of pseudo-EMD include hypovolemia, tension pneumothorax, pericardial tamponade, and massive pulmonary embolism. Pseudo-EMD of extracardiac origin most often has narrow complex tachycardia initially, which can progress to bradycardia, with conduction abnormalities and QRS widening.

Treatment of PEA requires all general resuscitation measures, including CPR, intubation with assisted ventilation, IV access, and repeated administration of vasopressors. Initial assessment also should include vascular Doppler ultrasound, echocardiography, or PETCO2 monitoring to distinguish EMD from pseudo-EMD. This is important because volume loading or continuous vasopressor infusion, which is not typically used in routine cardiac arrest resuscitation, may be helpful in cases of pseudo-EMD. In contrast, the routine use of atropine during PEA, previously a mainstay of drug therapy, is not indicated. PEA thought to result from a supraventricular tachycardia (SVT) should be immediately cardioverted. These interventions alone are generally inadequate, unless the underlying cause of PEA is primary respiratory arrest...
or SVT. Successful resuscitation of patients with PEA hinges on rapid diagnosis and treatment of the underlying cause. Physical examination may provide valuable clues to the underlying cause (Table 8.4). In hypoxia and hypovolemia, the diagnosis is based on response to empirical therapy, whereas other causes such as pericardial tamponade, tension pneumothorax, and hypothermia can be definitively diagnosed during resuscitation.

### Asystole

Asystole represents complete cessation of myocardial electrical activity. Although asystole may occur early in cardiac arrest as a consequence of progressive bradycardia, asystole generally represents the end-stage rhythm after prolonged cardiac arrest caused by VF or PEA. Because the potential exists for an organized rhythm or VF to appear as asystole in a single lead—if the rhythm vector is completely perpendicular to the lead vector—asystole should be confirmed in at least two limb leads. Although asystole may be difficult to distinguish from extremely fine VF, routine countershock of asystole has not been shown to improve survival.

Treatment of asystole requires general resuscitation measures, including CPR, intubation with assisted ventilation, IV access, and repeated administration of vasopressors. Available evidence has indicated that routine administration of atropine is not beneficial. Extensive research has shown that asystole in the out-of-hospital setting seldom responds to pacing. To be effective, pacing must be initiated within several minutes of arrest.

### Extracorporeal Cardiopulmonary Resuscitation

Despite lack of supporting evidence from randomized trials, use of ECPR or venoarterial ECMO as a rescue therapy for refractory adult and pediatric in-hospital cardiac arrest is a well-established practice in many specialized centers. Observational and case-control studies have suggested benefit in selected patients with refractory out-of-hospital cardiac arrest, reporting rates of survival with good neurologic function ranging from 11% to 33%. Timely arterial and venous access, placement of canulas, and initiation of ECPR support is critical to success. When used, ECPR is most successful when flow is initiated within 60 minutes of cardiac arrest onset. Survivors typically require 2 to 5 days before they can be being successfully weaned from ECMO support. Common complications include coagulopathy, hemorrhage, limb ischemia, vascular injury; renal replacement therapy, and stroke. The implementation of an ECPR program for refractory out-of-hospital cardiac arrest is expensive and resource-intensive and requires a significant amount of training and coordination among EMS providers, receiving EDs, designated specialties, and participating ICUs to be successful. More research is needed to determine the feasibility and value proposition of implementation outside of specialized centers.

### OUTCOMES

#### Post–Cardiac Arrest Care

Resuscitation of a cardiac arrest victim does not end with ROSC. Management includes rapid diagnosis and treatment of the disorders that caused the arrest and complications of prolonged global ischemia. Simultaneous management of these two entities makes caring for a post–cardiac arrest patient particularly challenging. A comprehensive, goal-directed program of post–cardiac arrest care is necessary to optimize survival and neurologic recovery.

#### Hypothermic Targeted Temperature Management

Hypothermic targeted temperature management (HTTM) in comatose survivors of cardiac arrest has been shown to improve survival and functional outcome in two modestly sized, prospective randomized clinical trials. These studies enrolled only comatose survivors of out-of-hospital cardiac arrest that was witnessed arrest and had an initial rhythm of VF. The time to achieve target temperature (<34°C [93.2°F]) ranged from less than 2 hours to a median of 8 hours (interquartile range, 4–16 hours), suggesting a broad therapeutic window. HTTM was maintained for 12 to 24 hours, followed by gradual rewarming over 12 to 24 hours. A subsequent large, multicenter international randomized clinical trial of post–cardiac arrest HTTM included all presenting rhythms except unwitnessed asystole and found that outcomes with a target temperature of 33°C (91.4°F) were not superior to those with a target temperature of 36°C (96.8°F). In this study, target temperature was maintained for 28 hours, followed by gradual

ECMO, Extracorporeal membrane oxygenation.
rewarming at 0.5°C (32.9°F)/hr and then maintenance of temperature below 37.5°C (99.5°F) for 72 hours post-ROSC. Although these parameters provide guidelines within which post–cardiac arrest HTTM is effective, additional preclinical and clinical data are needed to determine the optimal method of temperature control, time to achieve target temperature, target temperature, duration of therapy, and rate of rewarming. We recommend that emergency clinicians provide HTTM to comatose adult patients who achieve ROSC following cardiac arrest, independently of presenting cardiac rhythm (shockable vs. nonshockable) and location (OHCA [out-of-hospital cardiac arrest] vs. IHCA [in-hospital cardiac arrest]). Furthermore, emergency clinicians should select and maintain HTTM at a constant temperature between 32°C and 36°C (89.6°F and 96.8°F) for 24 hours after achieving that target temperature.  

Although there are no absolute contraindications, relative contraindications may include another obvious reason for coma (eg, drug overdose, status epilepticus), known end-stage terminal illness, and a preexisting do-not-resuscitate status. In each of the two randomized HTTM trials, the rates of complications, including bleeding, were not statistically different between groups. Specifically, thrombolytic therapy does not preclude the use of hypothermia.

When the decision is made to treat the comatose post–cardiac arrest patient with HTTM, efforts to achieve and maintain target temperature should begin in the ED, when feasible. However, prehospital cooling after ROSC using cold IV saline has not been shown to improve outcomes in two prospective randomized clinical trials. 26–27 In the ED, practical methods of rapidly inducing hypothermia include ice packs (applied to the neck, inguinal areas, and axilla), fan cooling of dampened exposed skin, cooling blankets underneath and on top of the patient, and disabling areas, and axilla), fan cooling of dampened exposed skin, cooling blankets underneath and on top of the patient, and disabling of ventilator warming circuits. Rapid IV infusion of limited volumes (1–2 L) of 4°C (39.2°F) saline facilitates induction of hypothermia, but additional measures are needed to maintain hypothermia.

No one cooling strategy or device has been demonstrated to result in superior clinical outcomes. 28 A number of automated surface cooling devices are now available that use chest and thigh pads and continuous temperature feedback from bladder or esophageal temperature probes. Although more invasive, automated endovascular cooling systems are also available that require placement of a central venous catheter and offer tighter control of temperature at target (SD [standard deviation] usually <0.3°C [32.5°F]). 28,29 Shivering, which inhibits cooling, can be prevented with sedation and neuromuscular blockade. If neuromuscular blockade is continued during the maintenance phase of therapeutic hypothermia, continuous electroencephalographic monitoring is strongly encouraged to detect seizures, a common occurrence in post–cardiac arrest patients (5%–20%). 25 Target core body temperature is best monitored by an indwelling, temperature-sensitive bladder catheter or esophageal temperature probe. Although the optimal duration of post–cardiac arrest hypothermia is unknown and may be related to the total ischemic time, target temperatures are typically actively maintained for at least 24 hours, followed by gradual rewarming over 12 to 16 hours. 25 Postarrest hypothermia is also discussed in Chapter 7.

**Coronary Angiography and Primary Percutaneous Coronary Intervention**

An immediate concern in a comatose cardiac arrest survivor is whether the patient has an acute coronary syndrome (ACS). Diagnosing ACS in an unconscious patient after cardiac arrest presents a unique challenge. A standard 12-lead ECG should be obtained as soon as feasible after ROSC, with additional right-sided and/or posterior leads as indicated. In one study, 50% of patients achieving ROSC after out-of-hospital cardiac arrest were found to have acute coronary occlusion on cardiac catheterization; more than 10% of them did not have ST segment elevation. Subsequent studies have reported that successful, immediate PCI is associated with improved hospital survival in post–cardiac arrest patients, with or without ST segment elevation. 31

Immediate PCI is indicated for post-ROSC patients with demonstrated ST segment elevation myocardial infarction (STEMI) and should progress via established systems of care. 32 OHCA patients are often initially comatose, but this should not be a contraindication to consider immediate angiography and PCI. Although the initiation of TTM should not delay PCI, it can often be accomplished simultaneously and in concert with interventional cardiology. 33 When there is a high clinical suspicion of ACS without STEMI demonstrated on an ECG, rapid post-ROSC angiography and PCI, when indicated, have been associated with improved survival to hospital discharge when a noncardiac cause for OHCA is not obvious. 34

When PCI is indicated but not available, transfer of post–cardiac arrest patients to a center capable of PCI or fibrinolytic therapy should be considered. Relative exclusion criteria for fibrinolytic therapy unique to the post–cardiac arrest patient include evidence of significant CPR trauma such as pneumothorax, flail chest, or pulmonary contusion with hemorrhage. The effects of TTM on the efficacy and complications of fibrinolytic therapy in postarrest patients have not been formally studied. However, an initial randomized TTM trial where fibrinolytics were given to approximately 50% of enrolled subjects demonstrated no increase in complications compared to controls.

Although the immediate post–cardiac arrest period is characterized by a hypocoagulable state, it is rapidly replaced by a hypercoagulable state for up to 72 hours as the post-ROSC surge of activated protein C abates. 33 Dual anticoagulant and antiplatelet therapy (aspirin and a P2Y12 inhibitor) should be strongly considered for postcardiac patients with diagnosed or suspected ACS in the absence of contraindications. 34–35 Recent clinical evidence has suggested that ticagrelor results in more effective platelet inhibition than clopidogrel in post–cardiac arrest patients treated with HTTM. 36 There is no proven benefit of prophylactic antiarrhythmic therapy or continuous infusion of an antiarrhythmic drug that has been associated with restoration of a stable rhythm during CPR. Concomitant therapies (eg, nitrates, beta blockers) are best performed in conjunction with careful hemodynamic monitoring. If indicated, IV preparations of nitrates and short-acting beta blockers (eg, esmolol) should be used because they have a brief duration of action and are easily titrated. In patients with new left bundle branch block, right bundle branch block with left anterior or posterior hemiblock, second-degree type II block, or third-degree block, transthoracic pacing pads should be applied in case they are needed to treat bradyarrhythmic rhythms. Placement of a transvenous pacing catheter may be considered, but is less commonly done with the increasing use and demonstrated efficacy of transthoracic cardiac pacing.

Inadequate oxygen delivery (DO₂) causes cells to convert to anaerobic metabolism, resulting in increased lactate production (dysoxia). Continued resuscitation efforts are aimed at optimizing DO₂ to prevent subsequent multiorgan dysfunction and recurrent arrest. However, supranormal arterial oxygen partial pressure (>300 mm Hg) can exacerbate oxidative brain injury during the first minutes to hours after cardiac arrest. Therefore, the fraction of inspired oxygen (FIO₂) can be titrated to the minimum concentration required to maintain an arterial oxyhemoglobin saturation around 94%. This level of oxygenation avoids detrimental hyperoxia while ensuring appropriate oxygen delivery. 37

Serum lactate levels provide an indirect measure of whether DO₂ is adequate to prevent anaerobic metabolism. A single lactate

---

**Fig. 8.3.** Goal-directed postarrest treatment algorithm. "Hypothermic targeted temperature management (HTTM) is indicated in comatose survivors of witnessed cardiac arrest who had a presenting rhythm of ventricular fibrillation. It may also be effective in patients resuscitated from other cardiac arrest presentations. Relative contraindications include uncontrolled bleeding, preexisting coagulopathy, another obvious reason for coma (e.g., drug overdose, status epilepticus), known end-stage terminal illness, and a preexisting do-not-resuscitate status. initiation of HTTM is not a contraindication to thrombolytic therapy. CPB, cardiopulmonary bypass; CVP, central venous pressure; DO₂, oxygen delivery; ECG, electrocardiogram; Hb, hemoglobin; IABP, intraaortic balloon pulsation; MAP, mean arterial pressure; MI, myocardial infarction; NTG, nitroglycerin; PCWP, pulmonary capillary wedge pressure; PTCA, percutaneous transluminal angioplasty; SaO₂, arterial oxygen saturation; ScvO₂, central venous oxygen saturation; VO₂, oxygen consumption."
level is almost universally elevated after resuscitation from cardiac arrest. Detection of ongoing lactate production requires monitoring of serial lactate levels. Insufficient DO₂ also causes increased oxygen extraction, resulting in decreased mixed venous oxygen saturation (SvO₂). Low SvO₂ coupled with persistently elevated lactate levels indicates inadequate DO₂. Patients with prolonged duration of CPR and those who have received high-dose vasopressor therapy during CPR may develop impaired tissue oxygen extraction. In such patients, SvO₂ is abnormally high (venous hyperoxia) in the presence of inadequate DO₂ and likely represents a state of severe systemic shunting resulting in an increase in nonnutritive blood flow. Lactate levels in these cases are persistently elevated. Treatment includes carefully reducing any continuous infusion of vasopressors and providing more aggressive volume loading. The use of guided vasodilator therapy to recruit underperfused tissue beds, as well as consideration of mechanical adjuncts such as an intraaortic balloon pump or VA-ECMO, may also be necessary in this situation.

The use of combined hemodynamic and metabolic endpoints to guide resuscitation in the ED has been shown to improve the outcome of patients with septic shock states. Because the post–cardiac arrest condition represents a complex state of cardiovascular shock, the use of such goal-directed therapy is inherently valuable to reduce mismatches of oxygen delivery and consumption that cannot be determined by a simple physical examination and vital signs. The use of goal-directed hemodynamic therapy is relatively straightforward and can be frequently accomplished via noninvasive means. Bedside ultrasound can be used to visualize the left ventricle in real time, allowing for direct assessment of cardiac index and myocardial wall function. Furthermore, in mechanically ventilated patients, volume responsiveness can also be reliably evaluated by measuring the inferior vena cava collapse or passive leg raise. These dynamic noninvasive measures can guide volume expansion to maximize preload without inducing pulmonary edema.

When sonographic measures are unavailable, the placement of a supradiaphragmatic central venous catheter may be used to give further clinical context for intractable shock. If ScVO₂, a reliable surrogate for SvO₂, is abnormally low (<65%), but hemoglobin and SaO₂ values are normal, cardiac output is insufficient. Although central venous pressure (CVP) has limitations in certain disease states (eg, pulmonary hypertension), a CVP less than 8 mm Hg can be generally relied on to be fluid-responsive, and augmenting CVP to levels between 10 and 15 mm Hg ensures adequate preload in most patients. If intravascular volume is adequate and the patient has a mean arterial pressure of at least 65 mm Hg, unmet resuscitation goals should prompt therapy with an inotropic agent such as dobutamine while reperfusion strategies or mechanical adjuncts are considered.

The response to DO₂-optimizing interventions can be monitored by continuous or serial ScVO₂ measurements and serial lactate levels. An increase in ScVO₂, coupled with a decrease in lactate levels, indicates improved DO₂. An unchanging ScVO₂ level indicates the need to continue to increase delivery. Persistently elevated lactate levels and a low ScVO₂, despite maximum pharmacologic support and volume management, signal the need for additional interventions to optimize DO₂. Similarly, in patients with venous hyperoxia and elevated levels of lactate, the combination of these findings indicates severe microvascular dysfunction, which also leads to the accumulation of oxygen debt incompatible with survival. If oxygen debt continues to accumulate, the patient will be at increased risk of developing multisystem organ failure or death. Fig. 8.3 provides a goal-directed guide to care of the postarrest patient.

Hospital protocols and systems can be designed to ensure prompt transfer of post–cardiac arrest patients from the ED to the cardiac catheterization laboratory or an ICU, where intensive monitoring can guide subsequent therapy to achieve optimal patient outcomes. Unless prompt transfer to the ICU is anticipated and achieved, comprehensive post–cardiac arrest care should be initiated in the ED.

**KEY CONCEPTS**

- CPR quality is critical to successful resuscitation from cardiac arrest. Important benchmarks of quality CPR include compression rate between 100 and 120 compressions/min, compression depth of 5 to 6 cm, chest compression fraction of 80% or more, full chest recoil, and ventilation rate of 10 breaths/min.
- Restoration of adequate cardiac function is the defining factor of ROSC. Restoration of good neurologic function is the defining factor of successful resuscitation.
- Resuscitation of a cardiac arrest victim does not end with ROSC. Rapid diagnosis and proper management of the pathologic conditions that precipitated and resulted from the arrest, as well as goal-directed post–cardiac arrest care, can improve outcome.
- Immediate PCI is indicated in patients with demonstrated ST segment elevation MI following ROSC without regard to neurological status.
- Hypothermic targeted temperature management (32°–36°C [89.6°–96.8°F] for 24 hours) is the first and only post-ROSC intervention that has been shown to improve survival and functional outcome of comatose cardiac arrest survivors.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

8.1. Which of the following statements regarding the epidemiology of out-of-hospital cardiac arrest is true? A. Most patients surviving to hospital discharge will have persistent neurologic deficits. B. Of patients successfully resuscitated and admitted to the hospital, 75% will survive to hospital discharge. C. Return of spontaneous circulation with subsequent hospital admission occurs in less than 3% of cases. D. Ventricular fibrillation is estimated to be the initial rhythm in more than 50% of all cases. E. With the application of therapeutic hypothermia, up to 50% of successfully resuscitated patients may survive to hospital discharge with return to prearrest function.

Answer: E. It is estimated that 176,000 patients are treated for out-of-hospital cardiac arrest each year in the United States. The proportion of emergency medical services (EMS)–treated cardiac arrest patients with an initial rhythm of ventricular fibrillation (VF) has declined over time to 20% in recent US studies. There is tremendous variability in survival to hospital discharge after EMS-treated cardiac arrest, ranging from 3% to 16.7%. Recent US data have indicated an average survival rate to hospital discharge of 11%. Of patients surviving to hospital discharge, independent of neurologic status on presentation, 78% have good neurologic function.

8.2. A 75-year-old man presents with return of spontaneous circulation (ROSC) after 2 minutes of VF and successful defibrillation by EMS. The patient is unresponsive to verbal and painful stimuli. Vital signs on arrival are pulse, 120 beats/min, blood pressure, 130/70 mm Hg, respiratory rate, 10 breaths/min, temperature, 36°C (96.8°F), and oxygen saturation, 94%. The patient has intravenous access. The next most appropriate examination or procedure is:

A. Anteroposterior (AP) chest radiograph
B. Arterial blood gas (ABG)
C. Comprehensive neurologic examination
D. Electrocardiography  
E. Oxygen via nonrebreather mask

Answer: D. Acute coronary syndrome is a common cause of out-of-hospital cardiac arrest. Electrocardiography should be performed as soon as possible after ROSC to evaluate for ST segment elevation. Because it is impossible to determine survival or neurologic status in the immediate postarrest period, ST segment elevation myocardial infarction (STEMI) should be treated aggressively with percutaneous coronary intervention (PCI) independently of coma or other laboratory values such as those provided on ABG analysis. Oxygen saturations above 94% are adequate for tissue perfusion, and hyperoxia may be harmful. AP chest radiographs may be important to evaluate ventilatory status if the patient is unstable.

8.3. Which chest compression/ventilation ratio is recommended during adult resuscitation efforts performed by health care professionals before placement of an advanced airway?
A. 10:1  
B. 20:1  
C. 20:2  
D. 30:2  
E. None. Evidence has shown that chest compression–only cardiopulmonary resuscitation (CPR) is the most effective for health care providers.

Answer: D. A 30:2 compression/ventilation ratio is currently recommended for health care professionals in all adult resuscitation scenarios. Although recent evidence has suggested that chest compression–only CPR is effective when performed by bystanders in the out-of-hospital setting, there is inadequate evidence to recommend this as an alternative strategy for health care professionals, except when adequate personnel are present to provide compressions, ventilation, and other resuscitative activities.

8.4. Which of the following statements regarding hypothermic targeted temperature management in comatose survivors of cardiac arrest is true?
A. Gradual rewarming should occur over 4 hours.  
B. Pregnancy is an absolute contraindication.  
C. Prolonged pharmacologically induced paralysis is often required to control shivering.  
D. Target core body temperature should be 32° to 36°C.  
E. To achieve benefit, the target temperature must be reached in less than 30 minutes.

Answer: D. Induction of prolonged HTTM in comatose survivors of cardiac arrest has been shown to improve survival and functional outcome. A target temperature in the range of 32° to 36°C (89.6°–96.8°F) should be selected and maintained. The time to achieve this temperature has not been clearly defined, and it has been suggested that there is a broad therapeutic window. In the studies showing a benefit, maintenance of hypothermia occurred for 12 to 24 hours, followed by gradual rewarming over 12 to 24 hours. There are no absolute contraindications to induced hypothermia after arrest. Shivering, which inhibits cooling, can be prevented with sedation and pharmacologic paralysis. However, prolonged paralysis should be avoided because of the risk of unrecognized seizure activity in post–cardiac arrest patients.

8.5. For end-tidal pressure of carbon dioxide (PETCO2) to be a reliable indicator of cardiac output during cardiac arrest, which of the following must be present?
A. Mechanical chest compression must be performed.  
B. The patient must be in asystole.  
C. Patient must be normothermic  
D. The patient must have an endotracheal tube and relatively constant minute ventilation.  
E. Vasopressor therapy cannot be used.

Answer: D. Although PETCO2 will change in direct relationship to cardiac output, alterations in minute ventilation will concentrate or dilute the fixed amount of expired CO2, influencing the PETCO2 measured independently of cardiac output. Therefore, for PETCO2 to be a reliable indicator of cardiac output, minute ventilation must be held relatively constant. In addition, all studies demonstrating the relationship between PETCO2 and cardiac output have been performed with an endotracheal tube in place. The relationship of PETCO2 and cardiac output during CPR is not dependent on rhythm, mechanisms of chest compressions, or temperature. High-dose vasopressor therapy can cause a decreased in cardiac output during CPR, despite increased myocardial blood flow, which results in a decreased PETCO2.
Fever in the Adult Patient

**SECTION TWO**

Signs, Symptoms, and Presentations

**CHAPTER 9**

**Fever in the Adult Patient**

Fever may be produced by a number of endogenous and exogenous substances termed pyrogens. Endogenous pyrogens include a variety of cytokines released by leukocytes in response to infectious, inflammatory, and neoplastic processes. Exogenous pyrogens include a large number of bacterial and viral products and toxins. Toxins induce fever by stimulating cells of the immune system to release endogenous pyrogens. These cytokines, such as interleukin-1 (IL-1), IL-6, tumor necrosis factor, and interferon, travel to the hypothalamus and induce the production of prostaglandin E2 (PGE2).

PGE2 raises the set point of the temperature range by a combination of effects, including peripheral vasoconstriction, increased metabolic heat production, shivering, and behavioral changes that conserve heat. Fever is maintained as long as the levels of endogenous pyrogens and PGE2 are high. There is also a variety of other humoral and neural pathways that modulate this basic response. Cyclooxygenase inhibitors, such as aspirin, decrease fever by blocking the production of PGE2. Age, malnutrition, immunosuppression, and chronic disease may also blunt the febrile response.

Moderate elevations of the body temperature may serve to aid host defenses by increasing chemotaxis, decreasing microbial replication, and improving lymphocyte function. Elevated temperatures directly inhibit the growth of certain bacteria and viruses. Fever also results in certain increased physiologic costs to the host, including increased oxygen consumption, metabolic demands, protein breakdown, and gluconeogenesis. These costs are particularly problematic in older adults, who typically have a smaller margin of reserve for any given body system. It is well established that the ability to develop fever in older adults is somewhat impaired. Older adults also are known to have lower baseline temperatures than younger adults. It has not been shown that treatment of fever with antipyretics has a beneficial effect on outcome or prevents complications. An intensive care unit (ICU)–based study compared intravenous acetaminophen to placebo in febrile critically ill patients. There was no difference in 28- or 90-day mortality. Treatment to reduce fever often makes febrile patients feel more comfortable, however.

The initial step in the process of fever is resetting of the thermostatic set point in the hypothalamus to a higher temperature while the actual body temperature remains normal. This mismatch of the thermostat with the “sensed” body temperature causes the patient to feel chilled (chills). If the chills are reported early to a caregiver and the temperature is taken, it is usually found to be normal or minimally elevated. To the examiner’s touch, the patient’s skin temperature will feel normal. The patient remains chilled until the body temperature rises to near the (elevated) hypothalamic set point. At this point, the patient no longer

**Perspective**

**Epidemiology**

Morbidity and mortality rates from febrile illnesses vary dramatically with age. Younger adults with fever usually have benign self-limited disease, with less than 1% mortality. The challenge in this group is to identify the rare meningitis or septic condition when confronted with a predominance of self-limited viral and focal bacterial diseases. Patients older than 65 years, or those with chronic disease who have fever, represent a group at high risk for serious disease. Morbidity and mortality rates in this group are significant. From 70% to 90% are hospitalized, and 7% to 9% die within 1 month of admission. Infection is the most common cause of fever in these patients, and most of these infections are bacterial in nature. Three body systems—the respiratory tract, urinary tract, and skin and soft tissue—are the target for more than 80% of these infections. The relative mortality and morbidity rates for any given infection are much higher in the geriatric population. For example, older adults are at 5 to 10 times greater risk for urinary tract infections and 15 to 20 times greater risk for appendicitis. Even viral illnesses that are generally not fatal, such as influenza, can be highly lethal in older adults.

**Pathophysiology**

Body temperature is normally controlled within a narrow range by the preoptic area of the hypothalamus. This range is usually 36.0° to 37.8°C (96.8°–100.0°F). There is a circadian rhythm within this range, with lower temperatures in the morning and higher temperatures in the late afternoon. Fever occurs when this normal range is reset to a higher value.

There is no consensus on the threshold core temperature that defines fever. The Centers for Disease Control and Prevention define fever as a core temperature greater than 37.8°C in the absence of fever-reducing medication. Others use a value of 38.0°C to define fever. However, there is near-universal agreement that a core body temperature of 38.3°C (100.9°F) represents a fever.

Fever is distinct from hyperthermia. Hyperthermia is an elevation of the temperature related to the inability of the body to dissipate heat. Most cases of temperatures higher than 41.0°C (105.8°F) are a result of hyperthermia, but febrile illness also is considered.

In the anterior hypothalamus, neurons directly sense the blood temperature. Temperature is subsequently controlled by a combination of vasomotor changes, shivering, changes in metabolic heat production, and behavioral changes.

Fever results in certain increased physiologic costs to the host, including increased oxygen consumption, metabolic demands, protein breakdown, and gluconeogenesis. These costs are particularly problematic in older adults, who typically have a smaller margin of reserve for any given body system. It is well established that the ability to develop fever in older adults is somewhat impaired. Older adults also are known to have lower baseline temperatures than younger adults. It has not been shown that treatment of fever with antipyretics has a beneficial effect on outcome or prevents complications. An intensive care unit (ICU)–based study compared intravenous acetaminophen to placebo in febrile critically ill patients. There was no difference in 28- or 90-day mortality. Treatment to reduce fever often makes febrile patients feel more comfortable, however.

The initial step in the process of fever is resetting of the thermostatic set point in the hypothalamus to a higher temperature while the actual body temperature remains normal. This mismatch of the thermostat with the “sensed” body temperature causes the patient to feel chilled (chills). If the chills are reported early to a caregiver and the temperature is taken, it is usually found to be normal or minimally elevated. To the examiner’s touch, the patient’s skin temperature will feel normal. The patient remains chilled until the body temperature rises to near the (elevated) hypothalamic set point. At this point, the patient no longer...
Although the differential diagnosis of fever is broad, most of the treatable causes are of infectious origin. Most of these causes of fever may be diagnosed by careful history and physical examination alone. Age and the presence of underlying medical conditions can substantially influence the evaluation and subsequent decision making regarding management.

An approach to the diagnosis and management of the healthy, otherwise stable adult patient with acute febrile illness is shown...
**Approach**

Critically, IV, febrile patient. The ill to infection. Of the cases of functional decline in nursing home patients, 75% are a result of infections. Abnormal vital signs, especially significant tachypnea and hypotension, may be the only sign of severe infection. Abnormal atypical symptoms help identify possible causes and severity of illness. In these populations, subtle changes may cause atypical signs and symptoms in older adults or immunosuppressed patients. In these populations, subtle changes may cause atypical signs and symptoms in older adults or immunosuppressed patients.

**Fig. 9.1.** Approach to the critically ill febrile adult patient. IV, Intravenous.

in **Fig. 9.2.** In younger and otherwise healthy adults, self-limited, localized bacterial infections or benign systemic viral infections are usually the cause of fever. The challenge with this group is to identify the rare life-threatening illness, such as meningococcal meningitis, meningitis, or systemic methicillin-resistant *Staphylococcus aureus* (MRSA) infection.

In the older or chronically ill population, fever is frequently a sign of severe illness. Usually, the cause is infectious. In addition to the most common infectious causes of illness (eg, respiratory, urinary, or skin sources), infections such as meningitis, cholecystitis, appendicitis, and diverticulitis are considered and may cause atypical signs and symptoms in older adults or immunosuppressed patients. In these populations, subtle changes in behavior may be the only sign of severe infection. Abnormal vital signs, especially significant tachypnea and hypotension, may portend a complicated and severe course. Of the cases of functional decline in nursing home patients, 75% are a result of infection.

### Symptoms

The onset of the fever, its duration and magnitude, and any associated symptoms help identify possible causes and severity of illness. Localizing symptoms such as dysuria or productive cough are especially helpful. The timing of the fever and its patterns may implicate certain diseases (eg, malaria). Recent or remote travel, chronic illnesses, past surgeries, hospitalizations, and treatment modalities may raise the suspicion of exotic or nosocomial infections. The presence of prosthetic heart valves or any indwelling device may be critical to the diagnosis. With the emergence of community-acquired MRSA, it is important to seek a history of skin infections in close family members or other close contacts. MRSA should also be considered in military personnel, prisoners, and persons involved in competitive sports that involve close contact.

Also important in the medical history is a list of all the patient's medications, including any antipyretic medications. Family members are frequently an important source of information for older and very young patients.

Atypical symptoms of illness are common in older patients. Pneumonia or urinary tract infection in the older patient may be heralded only by a change in mental status, difficulty ambulating, or some other functional decline. Dysuria, frequency, and flank pain often are absent entirely in older adults with a urinary tract infection. Patients with pneumonia may inconsistently demonstrate productive cough or shortness of breath. Other frequent but nonspecific symptoms include anorexia, weight loss, weakness, lethargy, nausea, and recurrent falls. A history of cancer with recent chemotherapy or radiation therapy may be a clue to leukopenia or another immunodepressed state. Assessment of the patient's baseline mental and physical function often relies on the reports of others who know the patient well.

### Signs

The presence and magnitude of fever are important elements of the examination, but the older, very young, or chronically ill patient may not mount a febrile response to significant infection. Temperatures may fluctuate, and rechecks may be necessary.

Although the most accurate measure of core body temperature is thought to be via the thermistor of a pulmonary artery catheter, in the ED, rectal temperature measurements or, when a Foley catheter is indicated, bladder thermistors are the most practical and accurate. Axillary and tympanic temperatures often are unreliable. Oral temperatures may be transiently distorted by recent ingestion of hot or cold liquids, smoking, or hyperventilation. For example, rectal temperatures are typically 0.7° to 1.0°C higher than oral temperatures.

Fever is inconsistently associated with tachycardia and tachypnea. As a rough estimate, the heart rate may increase by 10 beats/min for each 0.55°C- (1°F-) rise in temperature. Relative bradycardia may be caused by medications such as beta blockers, but also can suggest factitious or drug-related fevers, typhoid fever, brucellosis, or leptospirosis. Frank bradycardia may occur with rheumatic fever, Lyme disease, viral myocarditis, and endocarditis. The respiratory rate may increase 2 to 4 breaths/min/°C. More significant tachypnea may be caused by respiratory infection or the acidosis related to shock.

In many patients, the examination is directed by the patient's localization of symptoms. The head and neck examination focuses on treatable foci of infection, such as otitis media, sinusitis, pharyngitis, peritonsillar abscess, retropharyngeal abscess, and dental infections. A muffled, so-called hot potato voice with severe sore throat may be a clue to adult epiglottitis or upper airway abscess. Fundoscopy rarely may reveal evidence of disseminated candidiasis, miliary tuberculosis, endocarditis, toxoplasmosis, or leukemia.

The neck is examined for lymphadenopathy, masses, or thyroid pathology (thymomegaly or mass). Nuchal rigidity or pain on flexion of the neck is a useful sign for meningismus, if present, but may not be prominent in many patients, particularly the very young or debilitated patient, even if meningitis is present. Conversely, cervical arthritis or Parkinson disease may cause preexisting nuchal rigidity.

The lungs are examined for rales, pleural rubs, or dullness to percussion. Localized rales or rhonchi may be subtle clues to the presence of pneumonia. The presence of concomitant chronic obstructive pulmonary disease or congestive heart failure, as...
well as poor respiratory effort, may hamper the diagnosis of pneumonia in older adults. The heart is examined for pericardial rubs or new murmurs.

The abdominal examination may be deceptively benign in older patients, patients with diabetes, or patients taking immunosuppressive drugs or steroids. When indicated by history or other findings, a rectal examination should be performed to check for evidence of enteritis, perirectal abscess, or prostatitis. The external genitalia examination may reveal evidence of a Bartholin abscess, urethral or vaginal discharge, or evidence of epididymitis or orchitis. In women, symptoms of lower abdominal pain, vaginal discharge, and dyspareunia suggest the need for a pelvic examination to evaluate for pelvic inflammatory disease or tuboovarian abscess.

![Fig. 9.2. Approach to the stable adult with an acute febrile illness. ANA, Antinuclear antibody; CBC, complete blood count; CT, computed tomography; CXR, chest x-ray; ESR, erythrocyte sedimentation rate; IVF, intravenous fluids; PPD, purified protein derivative; RF, rheumatoid factor; UA, urinalysis. (Modified from Holder BM, Ledbetter C: Fever of unknown origin: an evidence-based approach. Nurse Pract 36:46–52, 2011.)](image-url)
The skin and extremities should be evaluated for rash, petechiae, joint inflammation, or evidence of soft tissue infection. In the absence of trauma, tenderness over the long bones or the spine may be evidence of osteomyelitis or neoplastic processes. Older adults and bedridden patients should be checked for the presence of pressure sores or decubitus ulcers.

Ancillary Testing

Ancillary testing is directed by the history and physical examination. The two most useful ancillary tests, especially in older patients, are urinalysis and chest radiography. Chest radiographs are often helpful in the diagnosis of pulmonary infection but may be difficult to interpret in the patient with concurrent chronic obstructive pulmonary disease, congestive heart failure, dehydration, or other chronic lung disease. Urinalysis, although not foolproof, is highly accurate for detecting urinary tract infection, especially in men. Although the white blood cell count has been almost universally used in the evaluation of febrile patients, it lacks the degree of sensitivity and specificity to be of discriminatory value. The white blood cell count may incorrectly indicate serious infection when none is present or may be normal in the presence of life-threatening infection. Other indirect tests of infection and inflammation, such as the erythrocyte sedimentation rate, are also plagued with irregular sensitivity and poor specificity. Gram staining of appropriate specimens may be helpful, and cultures may be ordered, although the results do not influence emergency evaluation and treatment. With the emergence of MRSA, it has become increasingly important to obtain cultures from soft tissue skin abscesses in patients considered at risk for MRSA infection. In older or chronically ill patients with acute fever of unknown origin, blood and urine cultures are frequently appropriate. Outpatient blood cultures should rarely, if ever, be done. A patient ill enough to require blood cultures from the ED generally requires hospitalization and empirical antibiotic coverage. Cerebrospinal fluid evaluation should be considered when mental status changes are evident, or if headache, meningismus, or other unexplained neurologic symptoms are present and cannot be clearly accounted for by infection outside the central nervous system. Thyroid function studies may be helpful when thyroid storm is suspected. Arterial or venous blood gas studies may help identify patients with critical disease who require prompt treatment. Plain films of the abdomen are rarely indicated. Abdominal computed tomography (CT) is helpful if appendicitis, diverticulitis, cholecystitis, intestinal obstruction, perforated hollow viscus, or intraabdominal abscess is suspected. Ultrasonography may be helpful in the patient with potential cholecystitis. Cranial CT scanning may be indicated before lumbar puncture in febrile patients with focal neurologic findings or a suspected embolic source, such as endocarditis, to exclude mass lesions such as a tumor or brain abscess. Neither CT scanning nor lumbar puncture should delay administration of antibiotics in patients with suspected meningitis.

Diagnostic Algorithm

The differential diagnoses of infectious causes of fever are summarized in Table 9.1. The differential diagnoses of noninfectious causes of fever are listed in Box 9.1. However, differences in patient characteristics can cause different manifestations of the same illness. For example, pneumonia or a urinary tract infection manifests in and is tolerated by an 80-year-old very differently from that of a young adult. A careful history and physical examination, along with strategic ancillary testing, will allow the emergency clinician to determine when a critical condition is present and will determine the operational tempo of subsequent evaluation and treatment.

EMPIRICAL MANAGEMENT

Temperatures higher than 41.0°C can result in damage to neural tissue and require prompt and vigorous treatment with antipyretics and external cooling measures. Heat illness, a spectrum of disorders due to environmental heat exposure, can result in extreme hyperpyrexia and lead to heat stroke. Urgent external cooling with fans, mist, and other modalities are required and are discussed in Chapter 133. There is no evidence for an improved outcome by routine use of antipyretic therapy, such as acetaminophen, in patients without extreme temperature elevation, but it is not harmful, and patients often feel better when their temperature is lowered. Intravenous acetaminophen is as effective as oral acetaminophen and may be used in patients who are unable to take oral medication. Patients with signs and symptoms of sepsis require prompt evaluation and treatment. Sepsis is characterized by the systemic inflammatory response syndrome (SIRS), defined by the presence of two or more of these criteria: temperature greater than 38°C or less than 36°C; heart rate greater than 90 beats/min; respiratory rate greater than 20 breaths/min or Paco₂ less than 32 mm Hg; and leukocyte count greater than 12,000/µL, less than 4,000/µL, or more than 10% immature (band) forms. The reliability of SIRS has increasingly been questioned, and patients meeting the definition of sepsis using SIRS criteria must be further clarified because a patient with SIRS may have a mild, self-limiting infection or may have a more severe infection with the potential to progress to severe sepsis. Patients with severe sepsis or septic shock require aggressive management, including intravenous fluid administration and prompt antibiotic therapy (see Chapter 130). Patients with evidence of respiratory failure from shock or pneumonia require ventilatory support. Soft tissue infections of the head and neck may compromise the airway because of mechanical obstruction. These may require acute intervention to provide a secure airway.

In many cases, early empirical antibiotic therapy is appropriate. The choice of antibiotics is based on the likely cause of the fever as well as concomitant conditions, such as absolute neutropenia and end-stage renal disease. If a specific infection is subsequently identified, antibiotic therapy should be specific to that infection. With clinically severe illness in the absence of a clear source of infection, broad-spectrum coverage of gram-positive and gram-negative aerobic and anaerobic bacteria is indicated. In acutely ill febrile patients, especially those who are immunocompromised, antiviral and antifungal treatment are also frequently indicated.

DISPOSITION

Localized bacterial infections can often be treated with outpatient oral antibiotics. Relatively young, healthy patients with systemic viral illness can also be treated on an outpatient basis. These illnesses are often accompanied by vomiting and poor oral intake, and treatment in the ED with antipyretics, antinausea medications, and intravenous hydration may help prepare the patient for a successful outpatient course.

When no clear infection is identified in older patients or those with chronic illness, such as diabetes or chronic renal failure, admission to the hospital often is necessary to elucidate the possible causes of the presentation further. In this subset of patients, a diligent search for evidence of bacterial infection is required. Also, admission to an inpatient unit or ED observation unit may be advisable when fever or other systemic symptoms accompany a suspected MRSA infection. In patients with unexplained severe febrile illness, blood and urine cultures and broad-spectrum antibiotics are indicated to treat possible life-threatening...
infection until a specific disease process or pathogen is identified. Indwelling devices, such as percutaneous intravenous access ports, frequently require culture and may need to be removed. Neutropenic patients with fever require prompt treatment with broad-spectrum parenteral antibiotics, pending results of cultures. Patients with unstable vital signs or life-threatening infections may require admission to a special care unit if they cannot be adequately stabilized in the ED before admission.

• Younger adults with fever usually have benign self-limited disease, with low mortality. The challenge in this group is to identify the rare meningitis or septic condition when confronted with a predominance of self-limited viral and focal bacterial illness.
• For older patients, immunosuppressed patients, or those with chronic disease, fever indicates a high risk for serious disease. Temperature elevation may be minimal in these patients, who often are unable to mount a significant febrile response to serious infection. Bacterial infection is the most common cause of fever in these patients. Three body systems—the respiratory tract, urinary tract, and skin and soft tissue—are the target for more than 80% of these infections.
• Atypical symptoms of illness are common in older febrile patients. Altered mental status, difficulty with ambulation, frequent falls, and general functional decline may be the only signs of serious infection in older patients.
• The white blood cell count is not a discriminatory test for patients with fever, may incorrectly indicate serious infection when none is present, or may be normal in the presence of life-threatening infection.
• In febrile patients with serious signs and symptoms, early empirical antibiotic therapy is often appropriate. The choice of antibiotics is based on the likely cause of the fever as well as concomitant conditions, such as absolute neutropenia and end-stage renal disease.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Which three body systems are the target of more than 80% of bacterial infections in patients older than 65 years?

A. Central nervous system, respiratory system, genitourinary system
B. Central nervous system, respiratory system, skin and soft tissue
C. Central nervous system, urinary system, skin and soft tissue
D. Respiratory system, gastrointestinal system, genitourinary system
E. Respiratory system, genitourinary system, skin and soft tissue

Answer: E. Patients older than 65 years who present with fever represent a group at high risk for serious disease. Morbidity and mortality in this group are significant. Between 70% and 90% are hospitalized, and 7% to 9% die within 1 month of admission. Infection is the most common cause of fever in these patients, and most of these infections are bacterial in nature. More than 80% of these infections originate from the respiratory system, genitourinary system, and skin and soft tissue.

A 65-year-old man presents after “briefly collapsing” at a nearby bus stop. On arrival, he is confused, opens his eyes spontaneously, and follows simple commands. A medical information card found in his wallet reveals a history of hypertension and gout. Vital signs reveal a blood pressure of 95/50 mm Hg, heart rate of 95 beats/min, respiratory rate of 24 breaths/min, temperature of 41.5°C, and arterial oxygen saturation (SaO₂) of 95%. His finger-stick glucose level is normal. Pertinent physical examination findings include pallor, dry mucous membranes, Glasgow Coma Score (GCS) of 14, and ataxia. An intravenous bolus of normal saline is started. Which of the following is the most appropriate next step in the management of this patient?
A. Administer broad-spectrum antibiotics.
B. Mist the patient with water and place him in front of a fan.
C. Obtain a head CT scan.
D. Obtain an electrocardiogram.
E. Perform a lumbar puncture.

Answer: B. The two most important ancillary tests to perform in this patient? 
A. Blood culture and urine culture
B. Urinalysis and chest radiography
C. Urinalysis and white blood cell count
D. White blood cell count and chest radiography
E. White blood cell count and urine culture

Answer: D. Of the cases of functional decline (eg, difficulty ambulating, anorexia, decreased activity, new urinary incontinence) in nursing home patients, 75% are due to infection. A traumatic injury is less likely to cause functional decline than a urinary tract infection, which is more common, and likely overlaps more commonly with a traumatic injury.
**CHAPTER 10**

Weakness

Raveendra S. Morchi

**PERPECTIVE**

The complaint of weakness is common in emergency department (ED) patients and may be vague, subjective, and difficult to characterize. Up to 10% of ED visits are for generalized weakness, with a preponderance of the complaint among older adults. Over half of these patients are identified as having a serious condition, and the diagnoses span cardiovascular, pulmonary, metabolic, and infectious causes. The approach to generalized weakness includes an evaluation of causes of malaise or weakness due to other physiologic and psychological causes, including infection, dehydration, electrolyte disorders, cardiovascular disease, cancer, and even depression. Conditions that lead to the perception of weakness must therefore be differentiated from true loss of neuromuscular power. This chapter focuses on the initial evaluation of the generalized complaint of weakness and specific evaluation of acute neuromuscular weakness. The latter may be focal or generalized and may originate in central or peripheral nerves, the neuromuscular junction (NMJ), or myofibers themselves. Other chapters provide more detail on peripheral nerve (Chapter 97) and neuromuscular disorders (Chapter 98).

**Epidemiology**

The epidemiology of weakness is closely linked to the epidemiology of other diseases and medical conditions. Although weakness can be a presenting problem at all ages, patients who are older or chronically ill are more likely to develop weakness. Advanced diabetes, cardiovascular and pulmonary diseases, chronic infectious diseases, and cancer may produce neuromuscular weakness through secondary effects on the brain and neuromuscular system. Brain, spinal cord, peripheral nerve, and neuromuscular causes of weakness are much less common than weakness secondary to other medical conditions.

**Pathophysiology**

There are a number of physiologic considerations for the patient with diffuse weakness (Box 10.1). Alterations in plasma volume or composition, decrease in red cell numbers or cardiac function, drop in systemic vascular resistance, increased metabolic demand (infection, toxin, endocrinopathy), and mitochondrial dysfunction (severe sepsis) can all produce nonlocalized weakness via inadequate substrate delivery or utilization by neurons and cardiac or skeletal myofibers. A global depression in central nervous system (CNS) activity from sedative effect or stimulant withdrawal can also present as generalized weakness. Focal weakness confined to one area in the face or body (left, right, distal, or proximal) indicates a localized problem arising within the corresponding area of the central or peripheral nervous system. Lesions involving the motor areas of the cerebral hemispheres may cause unilateral weakness, and lesions in the cerebral cortex outside the motor area may cause receptive or expressive aphasias and complex cerebral motor deficits such as apraxia. These are covered in Chapter 91. Peripherally, the spinal nerves extend from the anterior horn of the spinal cord and represent the anatomic origins of the lower motor neuron (LMN). The neuroanatomic distinction between LMNs and upper motor neurons (UMNs) is essential in localizing lesions.

**DIAGNOSTIC APPROACH AND ALGORITHM**

Conditions that affect the UMN produce signs that include spasticity to extension in the upper extremities, spasticity to flexion in the lower extremities, hyperreflexia, pronator drift, Hoffmann’s sign, and Babinski’s sign (upgoing toes). UMN signs signify a lesion within the cerebral cortex or corticospinal tract (CST) of the brainstem or spinal cord. Although these findings are not always detectable in the acute period, the presence of even one of them indicates pathology within the CNS.

Weakness caused by LMN dysfunction is often accompanied by flaccidity, decreased reflexes, fasciculations, or muscle cramps. Lesions in the anterior horn of the spinal cord and its axonal extensions at the nerve root and peripheral nerve produce these findings. Conditions that have only peripheral effects at the NMJ and muscle have preserved reflexes.

**Differential Considerations**

In the diffusely weak patient, consideration is first given to a systemic deficiency in substrate delivery to the nervous system or skeletal muscle unit. The emergency clinician should explore an appropriately detailed history regarding circumstances at onset, progression, exacerbating or alleviating factors, and any fluctuations in severity that may help discern if weakness is a result of cardiovascular disease, pulmonary insufficiency, metabolic disturbance, concurrent infection, toxic ingestion, medication imbalance, or cancer. Review of systems can reveal orthopnea and symptoms of congestive heart failure in the fatigued patient with significant cardiac disease, chronic blood loss in the anemic patient, or incontinence in an older adult with a urinary tract infection.

Vital sign abnormalities, including tachycardia, tachypnea, fever, hypothermia, or hypotension, prompt immediate intervention and a search for a systemic cause of the weakness. A general physical examination, including organ systems, skin, and mucous membrane examinations, may provide evidence of systemic disease. A cardiovascular examination can give the emergency clinician a sense of the adequacy of delivery of substrate to brain and muscle. In such patients, the neurologic examination will not demonstrate focal changes of the central or peripheral nervous system.

If by history, physical examination, and bedside ancillary testing the patient does not appear to have derangements in intravascular volume or cardiopulmonary function, metabolic abnormalities, or a source of infection, the investigation turns to a neural or primary muscular cause for weakness. Usually, these patients will have some asymmetric finding on their neurologic examination. The critical and emergent diagnoses for neuromuscular weakness are listed in Table 10.1.
BOX 10.1

Nonneurologic Weakness

Alterations in plasma volume (dehydration)
Alterations in plasma composition (glucose, electrolytes)
Derangement in circulating red blood cells (anemia or polycythemia)
Decrease in cardiac pump function (myocardial ischemia)
Decrease in systemic vascular resistance (vasodilatory shock from any cause)
Increased metabolic demand (local or systemic infection, endocrinopathy, toxin)
Mitochondrial dysfunction (severe sepsis or toxin-mediated)
Global depression of the central nervous system (sedatives, stimulant withdrawal)

Diagnostic Algorithm

Generalized weakness can be explored by determining the adequacy of circulation. This includes an evaluation of cardiac function (signs of ischemia or infarction), red cell numbers, oxygen saturation, and systemic vascular tone. Next, assess plasma volume and its composition. Dehydration and altered nutrient (glucose), electrolyte (Na, K, Ca), or waste product (CO₂, urea, bilirubin, ketoacid) levels can produce diffuse weakness. If substrate delivery and plasma composition appear sufficient, consider disturbances of cellular metabolic machinery secondary to an endocrinopathy, toxin, or mitochondrial dysfunction in the setting of infection. Although generalized weakness can present deceptively as a focal deficit, particularly in areas already weakened by prior neurologic insult, focal findings, such as lateralizing weakness, numbness, gait instability, or cranial nerve defects, should prompt a more detailed exploration of a potential neurologic cause.

Critical Diagnoses

Deciphering focal loss of muscle power means following the pattern of a patient’s weakness from the cortical neuron down through the CNS, peripheral nervous system (PNS), NMJ, and myofibers (Fig. 10.1). Common clinical patterns of weakness can be classified and assessed as discussed in the following sections.

Unilateral Weakness

Combination of Arm, Hand, or Leg With Ipsilateral Facial Involvement. This presentation is generally caused by a lesion in the contralateral cerebral cortex or the CSTs coursing down the corona radiata and forming the internal capsule. Mild forms can be limited to a loss of dexterity and coordination with hand movements. Moderate loss of power is termed paresis, and complete loss of motion is termed plegia. UMN signs are useful corroborative findings but may not always be present. Sensory disturbances commonly occur over the areas of weakness. Look for associated neglect, visual field cut, or expressive or receptive aphasia to localize the problem to the cortex. Patients with equal loss of strength to the face, hand, and leg are more likely to have a subcortical lesion disrupting all these fibers as they funnel close together in the internal capsule. Concomitant headache is suggestive of a brain hemorrhage or mass lesion. Sudden onset of this weakness pattern implies hemorrhage or ischemia, whereas a gradual onset may be seen in demyelination (eg, multiple sclerosis, acute demyelinating encephalomyelitis) or neoplasm (eg, metastases, astrocytoma, oligodendrogioma, ependymoma).

Combination of Arm, Hand, or Leg With Contralateral Facial Involvement. This pattern indicates a brainstem lesion. A careful cranial nerve (CN) examination can provide more clues. If the patient has contralateral facial findings, there will likely be ptosis (CN III or sympathetic fibers) or a facial droop with forehead involvement (CN VII nucleus). Signs of CN V, VI, VIII, IX, or XII dysfunction will help localize to a particular level within the brainstem.1 Cerebellar findings or nystagmus may also be present on examination. Sensory disturbances can parallel the weakness, and some patients will report double vision, trouble swallowing, slurred speech, vertigo, or nausea and vomiting. The CST courses ventrally through the brainstem, and extremity weakness with UMN signs in the involved limbs may accompany brainstem lesions. Depressed consciousness can also occur if the brainstem reticular activating system is involved. The two main underlying processes that cause unilateral extremity weakness with contralateral facial involvement are vertebrobasilar insufficiency and demyelinating diseases.

Combination of Arm, Hand, or Leg Without Facial Involvement. Before a patient is placed in this category, a careful examination of facial symmetry is required to determine that subtle facial droop or effacement of the nasolabial fold is not present. If there is truly no facial involvement, the source of extremity weakness without facial involvement is most likely to be a result of one of these processes:

- A lesion in the medial, contralateral, cerebral homunculus (over the area where the lower extremity is represented)
- A discrete internal capsule or brainstem lesion involving only the corticospinal rather than the corticobulbar tracts
- Brown-Séquard internal capsule or brainstem lesion if the patient also has contralateral hemibody pain and temperature sensory disturbances below the level of motor weakness
One Limb Only (Monomelic Weakness, Monoparesis, or Monoplegia). Isolated weakness of one extremity is usually caused by a spinal cord or peripheral nerve lesion. Examination for UMN signs in the affected limb will help uncover rare monomelic presentations of CNS lesions. If UMN signs such as hyperreflexia or spasticity are present, a careful evaluation is performed for facial weakness or involvement of the contralateral or other ipsilateral limb as indicative of a central process. If weakness is in the entirety of one lower limb, one should ensure that the patient does not have a contralateral pinprick level indicative of Brown-Séquard hemicord syndrome. Monomelic weakness is often the result of a radiculopathy, plexopathy, peripheral neuropathy, or NMJ disorder. See Table 10.1 for emergent and critical peripheral nervous system diagnoses.

The examination for monomelic weakness presentations includes detailed strength testing and determination of whether weakness localizes to one ventral nerve root myotome or one particular peripheral nerve within the limb. Reflexes with a
Peripheral nerve disorder may be diminished, not hyperactive. Although radiculopathies can occasionally be purely motor, most peripheral lesions have some sensory component to their presentation; therefore, a careful sensory examination in the distribution of dorsal nerve root dermatomes and peripheral nerves is essential. See Box 10.2 for a list of nonemergent causes of peripheral neuropathy.

If suspicion is low for a UMN source of isolated extremity weakness, reflexes are intact, and there are no sensory deficits to suggest a nerve or root problem, NMJ disorders are considered. In such cases, the weakness is often mild, fluctuating, and worse later in the day. It usually involves the proximal arm or leg muscles, wrist extensors, finger extensors, or ankle dorsiflexors. NMJ disorder–induced weakness with only monomelic symptoms will be an uncommon diagnosis in the ED. In older patients and others with significant cardiac risk factors, myocardial ischemia is considered if arm sensory symptoms or arm weakness that does not demonstrate measurable loss of motor power is reported.

Bilateral Weakness

Lower Extremities Only (Paraparesis or Paraplegia). The first consideration with this presentation pattern is a spinal cord lesion. If this is the case, UMN signs may be absent in the acute period. Because the lateral spinothalamic tracts (LSTs) run in proximity to the CST, patients with bilateral lower extremity weakness frequently have alterations to their perception of pain or temperature. Examination may reveal a loss of pinprick sensation to a particular spinal level within the thoracic cord or terminal first lumbar segment. The lesion may be as high as T2 without producing upper extremity findings. The main causes of anterior cord syndrome are external compression, ischemia, or demyelination. In the absence of UMN signs or a clear thoracic pinprick level, evaluation of perianal sensation, rectal tone, and urinary retention can identify deficits that point to cauda equina syndrome—compression of peripheral nerve roots running below the termination of the spinal cord. If the physical examination does not support a cord syndrome or cauda equina compression, the patient may have a peripheral neuropathy affecting the longest nerve tracts first. The acute presentation that is most concerning is Guillain-Barré syndrome (GBS). Rapid demyelination of peripheral nerves can result in symmetric weakness ascending from the feet. Sensory findings parallel the weakness, and reflexes should be decreased at some point in the patient’s clinical course.

Upper Extremities Only. This central cord pattern localizes to the central portion of the cervical spinal cord where corticospinal fibers designated for hand and arm strength are located. The patient may have pinprick sensory loss over the upper extremities from the involvement of crossing sensory axons destined for the contralateral LST. However, light touch sensation, mediated by the posterior columns, should remain intact. Causes of central cord syndrome include cervical spine hyperextension injuries and syringomyelia.

All Four Extremities Without Facial Involvement (Quadripareis or Quadriplegia). The obvious concern with this pattern is for a cervical spinal cord injury or process, but the patient is first assessed for medical conditions that produce global weakness. The more dense the extremity weakness, the more likely it is that the patient has a cervical spinal cord problem. Although all four extremities will test poorly for muscle strength, there is frequently some discrepancy between the lower and upper limbs in quadripareis.

Determination of sensory dermatomes by pinprick testing in the arms and hands, along with strength testing of specific myotomes, will allow localization of the level within the cervical spinal cord. One physical examination confounder with disorders that cause cord compression or ischemia is that upper extremity myotomes corresponding to the site of spine involvement will actually have LMN signs of flaccid weakness and decreased reflexes because anterior horn cells are involved at this particular level. However, UMN signs may be elicited below that level. A C5 lesion, for example, can cause diminished biceps reflexes but exaggerated triceps and patellar reflexes.

Bilateral extremity weakness may occur in patients with GBS that has ascended from the lower extremity peripheral nerve myelin sheaths to the upper extremities. In this case, the lower limbs are usually weaker than the upper limbs.

Proximal Portions of Extremities Only. Provided that there are no UMN signs and no sensory deficits, this pattern points to a myofiber disorder. Patients may report general fatigue or trouble raising the arms above the head, climbing stairs, or rising from a chair. The common acute and progressive causes of proximal muscular weakness are inflammatory diseases such as polymyositis or dermatomyositis, or necrosis, as in rhabdomyolysis from 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. Muscles are commonly but not always tender to palpation. Myositis patients can also have dysarthria and dysphagia from weakness of the pharyngeal muscles. Airway protective mechanisms may eventually be compromised.

Chronic or recurrent myofiber pathology includes abnormalities to anchoring proteins supporting fibrils to the cytoskeleton and cell membrane (eg, muscular dystrophies), dysfunctional ion channels responsible for depolarization of the muscle fiber cell (channelopathies such as hyperkalemic and hypokalemic periodic paralysis), or impaired ability to use carbohydrate and lipid energy sources (eg, metabolic myopathies, mitochondrial myopathies). The presentation of these varied conditions ranges from insidious and progressive to sudden onset and episodic. Occasionally, a patient with an NMJ disorder will demonstrate proximal extremity or neck muscle weakness mimicking myofiber disease.

Distal Portions of Extremities Only. This pattern is almost always caused by a peripheral neuropathy (see Box 10.2). Patients will have weakness and poor coordination, with fine movements of their feet or hands. If this type of distal weakness is present in both lower extremities only, the patient will most likely have a chronic peripheral neuropathy or an acute demyelinating neuropathy (GBS). The patient will also have some sensory disturbance over the feet. Examination for perianal sensory deficits or issues with fecal or urine continence will help exclude the compressive polyradiculopathy of cauda equina syndrome as a cause of bilateral distal lower extremity weakness. If only the fingers and hands are involved, evaluation for central cord syndrome is performed. Bilateral lower cervical radiculopathies or symmetrical polyneuropathies are possible but much less likely.
Facial Weakness Without Extremity Involvement

Isolated facial weakness will appear in one of two forms.

Unilateral Facial Droop. If the weakness is a result of a CN VII problem, unilateral weakness in the upper and lower halves of the face should be present on examination. Causes for an isolated CN VII neuropathy are Bell’s palsy, mastoiditis, and parotitis. The examination must confirm that there is no extremity involvement and that other CNs, cerebellar testing results, and visual fields are normal. This will ensure that a brainstem lesion is not causing the weakness.

Facial Weakness Not Limited to Cranial Nerve VII and Muscle of Expression. This will include some combination of ptosis, binocular diplopia, dysarthria, or dysphagia. It can be caused by a brainstem lesion, multiple cranial neuropathies, or NMJ problem. If there are no cerebellar findings, visual field deficits, sensory disturbances, or extremity UMN signs, posterior cerebral circulation and brainstem disorders are less likely, and an NMJ disorder is more likely. Dysfunction of one or more ocular, facial, or pharyngeal muscles will be the most common presentation for NMJ pathology. The history may indicate that the facial weakness is acute and progressive (botulism) or chronic and fluctuating (myasthenia gravis). Signs of these diseases can be determined by examining extraocular motion, facial expression, and soft palate rise. Generalized fatigue is often reported, and neck, extremity, and respiratory muscle weakness caused by involvement of these neuromuscular units may be present on examination.

Patients with an abnormality of the presynaptic release of acetylcholine (eg, botulism, Eaton–Lambert syndrome, organophosphate poisoning) can have autonomic ganglia involvement and hence abnormal pupillary response to light, dry mouth, fluctuations in heart rate and blood pressure, anhidrosis, or gastrointestinal and bladder dysmotility.

Facial weakness from cranial polyneuropathy manifests with more than one CN deficit not localizing to a brainstem level and without any other long tract signs. These patients may have a variant of GBs or irritation of multiple CNs after they have exited the brainstem and pierced through inflamed meninges or malignant skull base metastases.

PIVOTAL FINDINGS

These are found in patients who present with lower extremity weakness, with the consideration of GBs localizing to a brainstem level, and without any other long tract sign. Close monitoring of respiratory symptoms, including tachypnea or shallow respiration, should prompt evaluation for potential respiratory failure from diaphragmatic, intercostal, and accessory muscle fatigue. Consideration should be given to quantify respiratory effort with pulmonary function tests, intensive care unit (ICU) admission, and possible mechanical ventilation.

In any patient with a sudden onset of focal weakness, a vascular cause (occlusion or hemorrhage) should be strongly considered until proven otherwise by an adequate imaging study. The presence of a severe headache with unilateral weakness, or midline back pain with lower extremity weakness, alerts the emergency clinician to a compressive space-occupying lesion.

Patients with UMN signs have weakness that localizes to the spinal cord CST or above and are considered to have an emergent problem. They may be at risk for progression to sympathetic autonomic failure or obtundation from enlarging space-occupying spinal or cerebral lesions, respectively. The presence of anorectal or bladder insufficiency without another explanation suggests a UMN or cauda equina lesion. Laboratory tests are most useful for excluding nonneuromuscular causes of weakness (electrocardiography, measurement of hemoglobin, glucose, electrolytes, tropinin, and lactate levels, urinalysis). Two exceptions are the creatinine kinase level in inflammatory myositis and potassium level in channelopathies.

MANAGEMENT

The ED management of neuromuscular weakness is based on evaluating the underlying cause and managing the complications of weakness. Airway protection in obtunded patients or those with upper airway compromise is paramount. Neck and pharyngeal muscle weakness, for example, may herald a risk for aspiration. Diaphragmatic weakness and inadequate hypopharyngeal muscle control or respiratory muscle fatigue should prompt definitive airway protection by endotracheal intubation. During rapid sequence intubation (RSI), succinylcholine should be avoided in suspected cases of progressive denervation of muscle of more than a 3-day duration due to receptor upregulation and the risk for severe hyperkalemia. In this situation, we recommend rocuronium, a nondepolarizing neuromuscular blocking agent.

New quadriplegia or quadriplegia and hypotension without another cause is assumed to be caused by failure of autonomic sympathetic fibers in the cervical spinal cord. Consider a volume load and pressor support in addition to emergent imaging of this area. Although new weakness localizing to the spinal cord calls for immediate imaging, weakness from the spinal roots down does not always necessitate imaging in the ED unless cauda equina syndrome is suspected. Patients with suspected GBS need pulmonary function testing in admission to a critical care setting for further management. An infectious or metabolic trigger is sought in patients with myasthenic crisis. If the patient is currently on acetylcholinesterase inhibitors, consideration should be given to a cholinergic crisis. Be aware of medications that may worsen weakness in patients with NMJ disease (eg, aminoglycosides, quinolones, beta blockers). Rhabdomyolysis is treated with aggressive fluid resuscitation and intervention directed at the primary cause, if known.

DISPOSITION

Patients with generalized weakness should receive treatment and disposition based on the underlying diagnosis, ranging from discharge home after intravenous rehydration to ICU admission, with invasive hemodynamic monitoring and multiorgan support.

Patients with identified central vascular lesions, thrombotic or hemorrhagic, should be aggressively managed in the inpatient setting. Patients with mild LMN or myofiber weakness of benign origin may be discharged with close follow-up, provided that the condition is not thought to be progressing rapidly. Those with more severe or progressive LMN or myofiber weakness and any patient with new UMN weakness should be admitted for further testing. Patients with suspicion for ascending paralysis should be admitted to an ICU setting for close respiratory observation.

CHAPTER 10: QUESTIONS AND ANSWERS

10.1. A 65-year-old man with a history of atrial fibrillation, on warfarin, with a supratherapeutic international normalized ratio (INR) of 4, presents with sudden onset right leg weakness and back pain. On examination, he is tachycardic to 108 beats/min and has 3/5 weakness to the right hip flexors and extensors, knee flexors and extensors, as well as ankle dorsiflexion and great toe extension. However, ankle plantar flexion is preserved. His knee reflexes are absent, but Achilles reflexes are normal. He has a normal Babinski reflex and no spasticity. He has sensory deficits throughout the anterior and posterior parts of his proximal leg as well as the anterior lower leg and dorsum of the foot. His posterior lower leg and plantar surface, however, have normal sensation. Rectal tone is normal, and there is no urinary retention. His most likely diagnosis is:

A. Anterior cord syndrome from epidural hematoma
B. Cauda equina syndrome
C. Guillain-Barré syndrome
D. Hemorrhagic anterior cerebral artery (ACA) distribution stroke
E. Retroperitoneal hematoma with lumbar plexopathy

Answer: E. This patient has a spontaneous retroperitoneal hematoma compressing the lumbar nerve plexus.

10.2. A 45-year-old man has had gradual onset of progressive weakness to his face and trouble swallowing for 2 days. On examination, he has bilateral ptosis with dilated, poorly reactive pupils, bilateral upper and lower facial muscle weakness, poor soft palate rise, and slurred speech. His oral mucosa is dry. Arms and legs have 5/5 strength. He has no sensory deficits. He has a palpable distended bladder. His symptoms have not abated since onset, and they are getting worse. The most likely diagnosis is:

A. Brainstem stroke
B. Botulism
C. Muscular dystrophy
D. Myasthenia gravis
E. Organophosphate poisoning

Answer: B. This patient has acute onset of progressive neuromuscular junction weakness. He has autonomic findings of abnormal pupil response to light, dry oral mucosa from decreased salivary production, and a distended bladder. These imply that his problem is with the release of acetylcholine (ACh) rather than the nicotinic receptor. The latter would not have autonomic findings. The most appropriate cause of acute onset, progressive impairment in the release of ACh, as listed in the choices, is botulism.

10.3. A 23-year-old woman presented with the sudden onset of weakness to her face, arm, and leg 2 hours ago. On examination, she has weakness to her upper and lower face on the left. She cannot abduct her left eye. She has 3/5 strength to her upper and lower extremities on her right side. She has a right pronator drift and an upgoing toe on the right. Sensation is decreased in her right upper and lower extremities as well. There is no aphasia, neglect, or visual field deficit. The most likely diagnosis is:

A. Midbrain stroke because of cardioembolic stroke
B. Middle cerebral artery (MCA) distribution stroke
C. Multiple sclerosis
D. Myasthenia gravis
E. Pons stroke because of vertebral dissection

Answer: A. This patient has lower motor neuron (LMN) signs (fasciculations) and UMN signs (pronator drift and increased reflexes) in similar distribution. The combination of upper and lower motor neuron involvement make ALS the leading diagnosis among those listed. His dysphagia and inappropriate smiling are due to a release of the medulla from upper motor neuron regulation.

10.4. A 21-year-old man awoke this morning with weakness to his right hand and right foot. He admits to drinking heavily the night before and falling asleep on the floor. On examination, he appears well, with weakness to right wrist extension and thumb extension, as well as sensory deficits over the dorsal surface of his hand and first and third digits. He also has weakness to ankle dorsiflexion and great toe extension on the right. He has sensory deficits over the anterior lower leg and the dorsum of his foot. Biceps and ankle reflexes are intact, he has no pronator drift, and his toes are downgoing. His most likely diagnosis is:

A. Brainstem stroke
B. Brown-Séquard syndrome
C. Compressive neuropathy
D. MCA distribution stroke
E. Polyradiculopathy secondary to disk disease

Answer: C. He has radial nerve and peroneal nerve palsies because of compression while lying passed out on the floor for an unspecified time.

10.5. A 70-year-old man has had trouble swallowing and progressive weakness of his hands over the past 2 months. On examination, his speech is slurred, his voice is nasal, and he has fasciculations to his face, tongue, and over his pectoralis muscles and deltoids bilaterally. He has 4/5 strength to shoulders, biceps, triceps, and hand grip bilaterally. Stiffness to extension is present at both elbows. He has bilateral pronator drift and 3+ biceps reflexes. He tends to smile inappropriately. He has no sensory symptoms. The most likely diagnosis is:

A. Amyotrophic lateral sclerosis (ALS)
B. Brainstem stroke
C. Chronic demyelinating polyneuropathy
D. Parkinsonism
E. Polymyositis

Answer: A. This patient has lower motor neuron (LMN) signs (fasciculations) and UMN signs (pronator drift and increased reflexes) in similar distribution. The combination of upper and lower motor neuron involvement make ALS the leading diagnosis among those listed. His dysphagia and inappropriate smiling are due to a release of the medulla from upper motor neuron regulation.

REFERENCE
Cyanosis

Madonna Fernández-Frackelton

CHAPTER 11

PERSPECTIVE

Cyanosis is a blue or purple appearance of the skin or mucous membranes. This clinical finding is caused by inadequately oxygenated blood perfusing peripheral tissues or the presence of abnormal hemoglobin forms, which are unable to bind oxygen or supply adequate oxygen to end organs and tissues.

Epidemiology

Cyanosis is a relatively rare presenting chief complaint in the emergency department (ED) and is usually noted in patients with a hypoperfused state or known cardiopulmonary disease, including congenital heart disease. Although carbon monoxide poisoning and cyanide toxicity result in inadequate hemoglobin oxygenation and tissue hypoxia, these entities typically do not present with the clinical finding of cyanosis and are discussed in other chapters.

Pathophysiology

Cyanosis is evident on physical examination when the absolute amount of desaturated (unoxgenated) hemoglobin in the circulating capillary blood is elevated to approximately 5 g/dL. It is not caused by a percentage of desaturated total hemoglobin mass or decreased amount of oxyhemoglobin. For this reason, patients with a relatively low hemoglobin level exhibit cyanosis at a much lower partial pressure of oxygen (Pao2) and arterial oxygen saturation (SaO2) than those with normal hemoglobin levels. Cyanosis is an insensitive indicator of tissue oxygenation. Its presence suggests hypoxia, but its absence does not exclude it.

Abnormal hemoglobin forms contribute significantly to cyanotic disease. Under normal conditions, red blood cells (RBCs) contain hemoglobin with iron in the reduced ferrous state (Fe2+). Ferrous iron binds oxygen readily to create oxyhemoglobin, and it reverts to the ferrous state when oxygen is released. The iron molecule may be oxidized to the ferric state (Fe3+), spontaneously or by oxidative stress, to produce methemoglobin. This reaction impairs the ability of hemoglobin to bind and transport oxygen to and carbon dioxide from the tissues. The oxygen dissociation curve is shown in Fig. 11.1.

A number of variables can increase or decrease the hemoglobin affinity for oxygen. Methemoglobin shifts the curve to the left, resulting in tissue hypoxia and lactic acid production. Methemoglobin normally accounts for less than 1% of total hemoglobin.1 Cyanosis results when more than 1.5 g/dL of methemoglobin is present (~10%–25% of the total hemoglobin). Methemoglobin has a dark purple-brown or chocolate brown color, even when exposed to room air. It is normally reduced to ferrous (Fe2+) hemoglobin primarily by nicotinamide adenine dinucleotide (NADH)–cytochrome b5 reductase, an enzyme system present within RBCs. A secondary system dependent on nicotinamide adenine dinucleotide phosphate (NADPH) reductase uses glutathione production and glucose-6-phosphate dehydrogenase (G6PD) to reduce methemoglobin to ferrous hemoglobin. This secondary pathway normally plays a minor role but is accelerated by methylene blue.1

Primary methemoglobinemia is the result of congenital errors in enzyme metabolism caused by diminished levels of NADH reductase or an abnormally functioning enzyme. Patients may have cyanosis in a stable compensated state. Acquired methemoglobinemia occurs when methemoglobin production (hemoglobin oxidation) is increased beyond the capacity of NADH reductase activity. This is usually a result of a drug reaction. See Box 11.1 for common causes. Newborns are at risk for methemoglobinemia because their NADH reductase activity is relatively low compared with that of adults.

DIAGNOSTIC APPROACH

Differential considerations for patients with cyanosis are listed in Box 11.2.

Pivotal Findings

Symptoms

The onset, duration, time of day of symptoms, and any previous episodes should be noted. Precipitating factors may include exposure to cold air or water, high altitude, or exercise in patients with a history of cardiopulmonary disease. Additional history should include known congenital heart disease or cardiopulmonary disease, hypercoagulable states, and any family history of cyanotic or hematologic disease. A history of home or occupational exposures to fumes or chemicals should be obtained, including aniline, azo dyes (phenazopyridine [Pyridium]), phenacetin, and nitrates.2 A drug history should be reviewed, including use of prescription and over-the-counter medications, health food supplements, and herbal or alternative preparations. The potential of pseudocyanosis resulting from exposure to dyes, heavy metals, or topically absorbed pigments should be explored.

In infants, congenital heart disease is suggested by difficulty feeding, sweating, lethargy, poor weight gain, or respiratory distress. Episodic cyanotic events, or tet spells, may be seen in children with tetralogy of Fallot—ventricular septal defect, overriding aorta, pulmonic stenosis or atresia, and right ventricular hypertrophy with outlet obstruction. These patients have cyanosis, tachypnea, and anxiety owing to decreased pulmonary blood flow, with shunting of unoxgenated blood into the peripheral circulation.

Signs

There is significant interobserver variability in detecting cyanosis on physical examination. Room lighting and temperature may affect examination of the skin and mucous membranes. A patient’s natural skin tone, thickness, and pigmentation also may alter findings.

Central cyanosis is often secondary to the shunting of venous unsaturated hemoglobin into the arterial circulation or the
presence of abnormal hemoglobin. Central cyanosis is best seen on perioral skin, oral mucosa, or conjunctivae.

Peripheral cyanosis is secondary to vasoconstriction and slow flow of normally oxygenated hemoglobin in arterial blood, allowing for greater oxygen extraction by the tissues. Peripheral cyanosis affects capillary beds and typically is seen in the extremities and nail beds. Differential cyanosis may occur in the upper or lower (or the right or left) half of the body, with the remainder of the body appearing well oxygenated. This form of cyanosis is usually seen in patients with cyanotic heart disease with multiple anomalies.

Vital signs should be obtained from all patients. Temperature is typically normal. Blood pressure and heart rate vary, depending on the cause and acuity of cyanosis. Upper airway obstruction and other signs of respiratory insufficiency should be sought. Intermittent apnea in infants suggests central nervous system immaturity or a central lesion. Infants with cyanosis, increased respiratory depth, periodic apnea episodes, or diaphoresis with feeding may have congenital heart disease. Tachypnea (>60 breaths/min) in a newborn is nonspecific but may indicate a pulmonary disorder, congenital heart disease, infection, metabolic disorder, or gastrointestinal or central nervous system pathology.

The general appearance and mental status are evaluated. The head, eyes, ears, nose, and throat examination may reveal central cyanosis. Fundoscopic examination may detect dilated tortuous veins and papilledema in patients with cyanotic congenital heart disease. Jugular venous distention may be seen on the neck examination in patients with pulmonary edema.

The chest examination may reveal crackles, wheezing, or inadequate ventilation. Heart sounds should be assessed for tachycardia, abnormal rhythm, or gallops and the presence and quality of murmurs, especially in the newborn. Central pulse strength should be noted. The abdomen should be examined for the presence of hepatosplenomegaly, pulsatile mass, or abdominal bruise.

Extremity examination includes evaluation of the nail beds for peripheral cyanosis, strength and symmetry of distal pulses, and capillary refill. Evidence of chronic vascular disease, such as hair loss and temperature difference, should be noted. Clubbing of the nails may occur because of increased soft tissue and expansion of the capillary beds (Fig. 11.2). Clubbing may be idiopathic or hereditary but is usually the result of chronic hypoxemic states, such as cyanotic heart disease, infective endocarditis, pulmonary disease (eg, chronic obstructive pulmonary disease, cystic fibrosis) and some gastrointestinal disorders (eg, cirrhosis, Crohn’s disease, hereditary but is usually the result of chronic hypoxemic states, such as cyanotic heart disease, infective endocarditis, pulmonary disease (eg, chronic obstructive pulmonary disease, cystic fibrosis) and some gastrointestinal disorders (eg, cirrhosis, Crohn’s disease,
BOX 11.2

Differential Diagnosis of Cyanosis

I. Peripheral cyanosis
   A. Low cardiac output states
      1. Shock
      2. Left ventricular failure
      3. Hypovolemia
   B. Environmental exposure (cold)
      1. Air or water
   C. Arterial occlusion
      1. Thrombosis
      2. Embolism
      3. Vasospasm (Raynaud’s phenomenon)
      4. Peripheral vascular disease
   D. Venous obstruction
   E. Redistribution of blood flow from extremities
II. Central cyanosis
   A. Decreased arterial oxygen saturation
      1. High altitude (>8000 ft)
   2. Impaired pulmonary function
      a. Hypoventilation
      b. Impaired oxygen diffusion
      c. Ventilation-perfusion mismatching
         (1) Pulmonary embolism
         (2) Acute respiratory distress syndrome
         (3) Pulmonary hypertension
      d. Respiratory compromise
         (1) Upper airway obstruction
         (2) Pneumonia
         (3) Diaphragmatic hernia
         (4) Tension pneumothorax
         (5) Polycythemia
   B. Anatomic shunts
      1. Pulmonary arteriovenous fistulae and intrapulmonary shunts
      2. Cerebral, hepatic, peripheral arteriovenous fistulae
      3. Cyanotic congenital heart disease
         a. Endocardial cushion defects
         b. Ventricular septal defects
         c. Coarctation of aorta
         d. Tetralogy of Fallot
         e. Total anomalous pulmonary venous drainage
         f. Hypoplastic left heart
         g. Pulmonary vein stenosis
         h. Tricuspid atresia and anomalies
         i. Premature closure of foramen ovale
         j. Dextrocardia

Fig. 11.2. Symmetric clubbing. Shown here are equal cyanosis and clubbing of the hands and feet resulting from transposition of the great vessels and a ventricular septal defect without patent ductus arteriosus.

Interpretation of pulse oximetry is problematic in the setting of cyanosis (see Chapter 5). Assessment of peripheral pulses and capillary refill time can help determine whether poor circulation is the cause of low pulse oximetry. Pulse oximetry measures the light absorbance of tissue at two wavelengths, 660 nm (red, reduced hemoglobin) and 940 nm (infrared, oxyhemoglobin). The ratio of these two readings is the basis of the pulse oximetry calculation. Methemoglobin absorbs well at both wavelengths, resulting in a saturation reading of approximately 85%, regardless of the actual PaO₂ and SaO₂ values.

Arterial blood gas testing assesses SaO₂, often sampled when the patient is breathing room air (see Fig. 11.1). CO-oximetry measurements should be specifically ordered if carbon monoxide exposure or methemoglobinemia is suspected. Sulfhemoglobin is reported as methemoglobin on CO-oximetry so, if sulfhemoglobinemia is possible, measured oxygen saturation should be specifically determined. Devices designed to measure methemoglobin levels noninvasively (e.g., pulse CO-oximetry) may be useful but have decreasing accuracy at lower SaO₂ levels (<95%) and higher methemoglobin levels (>14%).

Other Diagnostic Modalities

Imaging
A chest radiograph should be ordered to evaluate lung fields for consolidation, infiltrates, effusions, and pulmonary edema. An abnormal cardiac silhouette and mediastinum may suggest congenital heart disease. In patients thought to have PE, an elevated D-dimer level may indicate the need for lower extremity venous Doppler ultrasound, computed tomography (CT) pulmonary angiography or, rarely, ventilation-perfusion scanning.

Electrocardiography and Echocardiography
An electrocardiogram should be obtained on all patients with a new presentation of cyanosis to assess for dysrhythmia and acute ischemic changes. Right axis deviation or right ventricular hypertrophy may be seen with significant cardiopulmonary disease (e.g., cor pulmonale, acute pulmonary hypertension). An

Laboratory and Ancillary Testing
The complete blood count is performed to assess for erythrocytosis, polycythemia, or anemia. A peripheral smear assesses RBC morphology and fragments, as well as the white blood cell differential count. A D-dimer level is indicated if pulmonary embolism (PE) is suspected as the cause of observed circulatory shock.

The peripheral blood typically appears chocolate brown in color. Normally, a small drop of blood placed on a white sheet or filter paper will turn bright red when exposed to 100% oxygen. No change in color is highly suggestive of methemoglobinemia.
CHAPTER 11 Cyanosis

Cyanosis should be suspected in patients with central cyanosis with facial, neck, and upper extremity swelling, with venous distention and plethora.

Critical Diagnoses
Acute cardiovascular and respiratory compromise are considered in patients with cyanosis and symptoms or signs of shock. The differential diagnosis includes acute heart failure, acute coronary syndrome, and hypovolemic or cardiogenic shock. In addition, consider acute respiratory insufficiency or failure, massive PE, exacerbation or decompensation in a patient with known congenital heart disease, or the first presentation of pediatric congenital heart disease.

Emergent Diagnoses
Methemoglobinemia is an infrequent cause of cyanosis but should be considered in patients without a history or physical findings suggestive of cardiovascular or pulmonary disease.

Sulfhemoglobinemia is a rare cause of cyanosis, usually occurring after exposure to hydrogen sulfide from organic sources, medications that are sulfonamide derivatives, or gastrointestinal sources (bacterial overgrowth). Strong consideration should be given to sulfhemoglobin toxicity in patients with cyanotic findings.

DIFFERENTIAL ALGORITHMS
Figures 11.3 and 11.4 outline approaches to the differential diagnosis and treatment of peripheral and central cyanosis, respectively. During the initial assessment, the emergency clinician should initiate oxygen therapy and follow steps to determine the cause of cyanosis. Clinical improvement with oxygen suggests diffusion impairment. Patients who do not respond to high-flow oxygen are more likely to have ventilation-perfusion ratio abnormalities, such as shunting from pulmonary consolidation or congenital heart disease with right-to-left shunting. Cardiac size and silhouette on a chest radiograph may suggest the presence of congenital heart disease. If heart size is normal, impaired pulmonary function, pulmonary embolus, or other noncardiac causes should be considered. If no improvement occurs with 100% oxygen therapy, the patient’s respiratory status should be reassessed and tension pneumothorax or upper airway obstruction considered. Pulmonary embolus should be considered and CT pulmonary angiography performed. If a patient exhibits no respiratory distress and remains resistant to oxygen therapy, cardiac shunting or abnormal hemoglobin forms should be considered and treated accordingly. Superior vena cava (SVC) syndrome should be suspected in patients with central cyanosis with facial, neck, and upper extremity swelling, with venous distention and plethora.

Fig. 11.3. Algorithmic approach to peripheral cyanosis. ABCs, Airway, breathing, circulation; ABI, ankle-brachial index; IV, intravenous.
Fig. 11.4. An algorithmic approach to central cyanosis. ABCs, Airway, breathing, circulation; ABG, arterial blood gas; AV, arteriovenous; CHF, congestive heart failure; CN, cyanide; CO, carbon monoxide; CTPA, computed tomography pulmonary angiography; CXR, chest radiograph; ECG, electrocardiography; Echo, echocardiography; G6PD, glucose-6-phosphate dehydrogenase; Hct, hematocrit; ICU, intensive care unit; IV, intravenous; LMWH, low molecular weight heparin; MetHgb, methemoglobin; O₂, oxygen; PaO₂, partial pressure of arterial oxygen; PE, pulmonary embolus; prn, as needed; RA, room air; SaO₂, arterial oxygen saturation; SulfHg, sulfhemoglobin; V/Q, ventilation-perfusion scan. ¹ Patients with chronic cyanotic heart disease may not require ICU care or even hospital admission. Disposition should be discussed with the patient’s cardiologist. ² The V/Q ratio may be determined when CTPA is unavailable or contraindicated.
and methemoglobin on CO-oximetry but who do not improve with methylene blue treatment.  

Polycythemia is defined as an elevated RBC mass from one of three causes. Polycythemia vera is a disorder of bone marrow stem cells with increased RBC mass, cyanosis, and splenomegaly. Patients may demonstrate hyperviscosity syndrome. Secondary polycythemia occurs with an appropriate or inappropriate increase of erythropoietin, physiologic response to chronic hypoxemia (<92% oxygen saturation), cyanotic congenital heart disease, cigarette smoking, or high-altitude exposures. Relative polycythemia is an increased RBC mass, often resulting from dehydration or reduced plasma volume.

Finally, vascular disease, such as Raynaud’s phenomenon, may cause peripheral cyanosis. Raynaud’s phenomenon occurs in 15% of the population, with a female predominance. Patients have an abnormal response to excessive cold or emotional stress, causing vasoconstriction, profound cold sensitivity, and recurrent events of sharply demarcated pallor or cyanosis of the digits (Fig. 11.5). Usually, the cutaneous arterial capillary beds of the fingers and toes are affected, but the tongue, ear, and other distal areas may also be affected.

**EMPIRICAL MANAGEMENT**

Administration of high-flow oxygen is the first therapy for patients with cyanosis. Any clinical improvement, or lack thereof, should be noted. Thereafter, consider an abnormal hemoglobin level and toxin-induced cyanosis because the administration of appropriate antidotes and systemic therapies may decrease morbidity.

Intravenous (IV) fluid resuscitation should be initiated in patients with hypovolemia. Treatment of congestive heart failure, arrhythmias, or poor cardiac output should occur as clinical conditions indicate. We recommend cardiology consultation for patients with congenital heart disease, who often have very abnormal responses to oxygen and conventional fluid therapy. If oxygenation compromise is sufficient to cause ischemic chest pain, prompt correction of the underlying hemoglobin abnormality is undertaken simultaneously with conventional treatment of the ischemia. Although several specific treatments are discussed here, the cause of the cyanosis may be elusive, and hospitalization is required in all but chronic stable cases.

**Specific Strategies**

**Methemoglobinemia and Sulfhemoglobinemia**

If cutaneous exposure to an inciting agent (ie, aniline dye) has occurred, complete decontamination with soap and water is recommended. The staff should use appropriate protective equipment. Urgent treatment with oxygen and methylene blue (1–2 mg/kg IV over 5 minutes) is indicated for patients with symptomatic hypoxia (eg, dysrhythmias, angina, respiratory distress, seizures, coma) or methemoglobin levels greater than 30%. Sulfhemoglobinemia is suggested when the laboratory reports an elevated methemoglobin level and the patient does not respond to methylene blue. Sulfhemoglobinemia is irreversible for the life of the erythrocyte. Treatment of sulfhemoglobinemia is supportive in addition to removing the causative agent. Transfusion of RBCs and exchange transfusion have been described as a treatment, but there are no controlled studies of this modality.

**Other Causes of Cyanosis**

Acute therapy for patients with symptomatic hyperviscosity syndrome and secondary polycythemia includes phlebotomy and volume expansion with isotonic crystalloid. The goal of therapy is to achieve a normal hematocrit (45%). Long-term therapy is focused on the underlying cause, and patients require referral to a hematologist.

Patients with SVC syndrome require further evaluation for a mediastinal mass or vascular abnormality. Conservative management with oxygen and elevation of the head of the bed often provide significant symptomatic relief. Vascular stenting may be necessary, and radiation or chemotherapy may be indicated in cases caused by malignancy. The Raynaud’s phenomenon is treated by warming the affected digits and extremities. Systemic vasodilating agents (eg, calcium channel blockers [nifedipine] or nitrates, endothelin antagonists, statins, phosphodiesterase inhibitors, botulinum toxin) may be useful in the acute setting, although data are limited. If there is no improvement of peripheral cyanosis with warming and administration of 100% oxygen, arterial insufficiency or occlusion may be present. In cases of critical limb ischemia, IV heparin should be considered in consultation with a vascular surgeon. Embolic sources, such as endocarditis and abdominal aortic aneurysms, should be considered. Vascular bypass, intraarterial thrombolysis, or stenting may be indicated.

Carbon monoxide and cyanide poisoning do not typically cause cyanosis and are covered elsewhere.

---

CHAPTER 11: QUESTIONS AND ANSWERS

11.1. Which of the following statements regarding methemoglobin is true?
A. Methemoglobin begins to produce cyanosis when its concentration reaches 25% of total hemoglobin.
B. Methemoglobin changes from dark purple to light red when exposed to room air.
C. Methemoglobin normally accounts for less than 1% of total hemoglobin.
D. Methylene blue accelerates the reduction of methemoglobin to hemoglobin.
E. The primary method of reducing methemoglobin to hemoglobin is glucose-6-phosphate dehydrogenase (G6PD)–dependent.

Answer: D. Methemoglobin normally accounts for less than 1% of total hemoglobin. Cyanosis results when MORE than 10% to 15% of the total hemoglobin is methemoglobin, which has a dark purple-brown color, even when exposed to room air. Methemoglobin is reduced to ferrous hemoglobin primarily by reduced nicotinamide adenine dinucleotide (NADH)–cytochrome b5 reductase, an enzyme system present in red blood cells. A secondary reduced nicotinamide adenine dinucleotide phosphate (NADPH)–dependent system uses glutathione production and G6PD to reduce methemoglobin to hemoglobin. This secondary pathway normally plays a minor role but is accelerated by methylene blue.

11.2. Which of the following conditions produces peripheral cyanosis?
A. Diaphragmatic hernia
B. High altitude > 8000 ft
C. Hypovolemia
D. Impaired oxygen diffusion
E. Pulmonary hypertension

Answer: C. Peripheral cyanosis is secondary to vasoconstriction and a slow flow of normally oxygenated hemoglobin in arterial blood, allowing for greater oxygen extraction by the tissues. Hypovolemia causes a low-flow state that can produce peripheral cyanosis. The remaining options would cause a central cyanosis secondary to decreased arterial oxygen saturation.

11.3. Which of the following conditions produces central cyanosis?
A. Hypothermia
B. Raynaud’s phenomenon
C. Shock
D. Venous insufficiency
E. Ventricular septal defect

Answer: E. Central cyanosis is caused by decreased arterial oxygen saturation, shunting of venous unsaturated hemoglobin into the arterial circulation, or the presence of abnormal hemoglobin. A ventricular septal defect causes shunting of deoxygenated blood from the right side of the heart to the left, with resultant decreased arterial oxygen saturation and central cyanosis. The remaining options would cause a peripheral cyanosis.

11.4. In the cyanotic patient, clinical improvement with supplemental oxygen is most suggestive of which of the following underlying processes?
A. Arterial emboli
B. Congenital heart disease with right-to-left shunting
C. Hyperventilation
D. Impaired oxygen diffusion
E. Ventilation-perfusion mismatching

Answer: D. Clinical improvement with oxygen suggests diffusion impairment. Patients who do not respond to oxygen are more likely to have ventilation-perfusion ratio abnormalities, such as shunting from pulmonary consolidation or congenital heart disease with right-to-left shunting. Arterial emboli will be affected by supplemental oxygen.

11.5. Which of the following statements regarding polycythemia is correct?
A. Polycythemia is defined as an elevated hemoglobin level.
B. Polycythemia vera may result from an increase in the erythropoietin level.
C. Patients may present with hyperviscosity syndrome.
D. Relative polycythemia occurs from high-altitude exposures.
E. Secondary polycythemia is often due to dehydration.

Answer: C. Polycythemia is defined as an elevated red blood cell (RBC) mass resulting from one of three causes. Polycythemia vera is a disorder of bone marrow stem cells with increased RBC mass, cyanosis, and splenomegaly. Patients may present with hyperviscosity syndrome. Secondary polycythemia occurs with an appropriate or inappropriate increase of erythropoietin, a physiologic response to chronic hypoxemia, cyanotic congenital heart disease, cigarette smoking, or high-altitude exposures. Relative polycythemia is an increased RBC mass, often resulting from dehydration or reduced plasma volumes.

11.6. Soon after receiving topical upper airway anesthesia with benzocaine, a patient becomes tachypneic and complains of chest pain. The patient is noted to be cyanotic. Supportive measures are initiated, and CO-oximetry reveals a methemoglobin level of 40%. Which of the following should be administered?
A. Benadryl
B. Hyperbaric oxygen
C. Methylene blue
D. Nitroglycerin
E. Thrombolytics

Answer: C. Methylene blue is the drug of choice for treating methemoglobinemia. It accelerates the reduction of methemoglobin to hemoglobin. Benadryl is an antihistamine and may be used to alleviate symptoms of allergy or anaphylaxis. Hyperbaric oxygen therapy can be used in severe cases of methemoglobinemia. Nitroglycerin is used to treat angina pectoris and may be used in the treatment of methemoglobinemia. Thrombolytics are used to dissolve blood clots and may be used in the treatment of methemoglobinemia.
Answer: C. Local anesthetics such as benzocaine, lidocaine, and prilocaine can cause an acquired methemoglobinemia. Urgent treatment with oxygen and methylene blue is indicated in such patients, especially when accompanied by symptomatic hypoxia (e.g., dysrhythmias, angina, respiratory distress, seizures, coma) and methemoglobin levels greater than 30%.

11.7. An otherwise healthy 35-year-old woman presents with headache, mild shortness of breath, and central cyanosis. She is currently taking trimethoprim-sulfamethoxazole and phenazopyridine for a urinary tract infection. She does not improve with supplemental oxygen. Her chest radiograph is normal. CO-oximetry shows a methemoglobin level of 28%. Her medications are withheld. The patient shows no improvement after 2 mg/kg of methylene blue is administered. Ongoing management should include which of the following treatments?
A. Calcium channel blockers
B. Hydroxycobalamin
C. Phlebotomy
D. Sodium thiosulfate
E. Supportive care

Answer: E. This patient has likely has sulfhemoglobinemia, a rare complication of the medication phenazopyridine (Pyridium). Standard CO-oximetry will report sulfhemoglobin as methemoglobin. Both sulfamethoxazole and phenazopyridine can also cause methemoglobinemia. Patients with an elevated methemoglobin level and no response to methylene blue likely have sulfhemoglobinemia, which is less severe than methemoglobinemia and only requires supportive care. Phlebotomy is the treatment for polycythemia. Sodium thiosulfate and hydroxycobalamin are both used to treat cyanide toxicity, and calcium channel blockers may be used to treat peripheral cyanosis resulting from vasospasm (Raynaud’s phenomenon).

11.8. Acute treatment for symptomatic hyperviscosity syndrome includes which of the following?
D. Heparin
E. Methylene blue
C. Nifedipine
A. Phlebotomy
B. Warm compresses

Answer: A. Patients with polycythemia and other conditions that increase the viscosity of blood may present with symptomatic hyperviscosity syndrome. Acute therapy for these patients includes phlebotomy and volume expansion with isotonic crystalloid. The goal of therapy is a normal hematocrit. Long-term therapy is focused on the underlying cause, and patients typically require referral to a hematologist.
Syncope is the sudden transient loss of consciousness with a loss of postural tone. It is a common presenting complaint in the emergency department (ED). Despite improved understanding of risk and outcomes, consensus on the diagnostic approach and disposition remains elusive. This is in part because of the varied causes of syncope and lack of definitive diagnostic studies available and because of confusion and lack of standard terminology to describe the disorder. Diagnostic accuracy relies largely on the synthesis of patient risk factors and reported symptoms, with limited reliance on the physical examination and ancillary testing.

**Epidemiology**

The prevalence of syncope in the general population is approximately 19%, with only half consulting a physician for evaluation. Syncope accounts for up to 3% of ED visits. Patients presenting to the ED for syncope appear to have a higher likelihood of a serious underlying cause than those presenting to other ambulatory settings. The admission rate is variable across EDs, with almost 50% of patients admitted to an inpatient or observation unit. Persons aged 65 years and older account for 80% of such admissions. The mortality rate at 1 month depends on the cause of syncope and comorbid conditions and can be nearly 5%. Up to 15% of children experience at least one episode of syncope.

Risk factors for syncope include cerebrovascular disease, cardiac medications, and hypertension. Most causes of syncope are benign and have favorable outcomes. Patients with preexisting cardiovascular disease and syncope from any cause are at the greatest short- and long-term risk of mortality. In patients with a cardiac history, 1 year after a syncopal episode, over one-third of the 7.6% death rate has been found to be cardiac related. Age, congestive heart failure, and coronary artery disease are key predictors of mortality in patients with syncope. In contrast, there is no increased risk of cardiovascular morbidity or mortality associated with neurally mediated (vasovagal), orthostatic, and medication-related syncope. Recurrence of syncope may be as high as 50% and is not correlated with age or gender.

Benign causes of syncope predominate in adolescents and young adults. Prospective outcome studies in children are incomplete, but it has been suggested that mortality rates are extremely low. Significant trauma may result from syncope and can contribute to increased risk of morbidity and mortality, particularly in older adults. The overall US medical cost of syncope has been estimated at $2.4 billion annually.

**Pathophysiology**

The final common pathway resulting in syncope is dysfunction of both cerebral hemispheres or the brainstem (reticular activating system), usually from acute hypoperfusion. Reduced blood flow may be regional (cerebral vasoconstriction) or systemic (hypotension). Loss of consciousness results in loss of postural tone, with the resulting syncopal episode. Less severe derangements may result in sensations of presyncope (near-syncope) or lightheadedness. Thus, presyncope and syncope may be considered on a continuum with shared causes, mechanisms, and outcomes. By definition, syncope is transient; therefore, the cause of central nervous system (CNS) dysfunction should likewise be transient. Persistent causes of significant CNS dysfunction may result in coma or depressed consciousness (see Chapter 13).

Hypoperfusion resulting in an approximately 35% or more reduction in cerebral blood flow usually produces unconsciousness, and any mechanism that adversely affects the components of perfusion (eg, cardiac output, systemic vascular resistance, blood volume, regional vascular resistance) can cause or contribute to syncope. The cause of syncope can be divided into three major classifications: neurally (or reflex) mediated, orthostatic hypotension mediated, and cardiovascular mediated. Causes of transient loss of consciousness that do not fall into the major syncope classifications presumably operate under different mechanisms; these include seizures, hypoglycemia, certain toxins and metabolic derangements, hyperventilation, primary neurologic conditions, and psychiatric disorders.

**DIAGNOSTIC APPROACH**

**Differential Considerations**

The potential causes of syncope are numerous and can be categorized according to their primary mechanism (Box 12.1). The first differential diagnostic consideration is to distinguish syncope from other causes of an apparent sudden loss of consciousness, especially seizure and uncommon disorders such as cataplexy. When syncope is established as the working diagnosis, the life-threatening causes, primarily cardiovascular in origin, are considered first. The principal serious causes of syncope are dysrhythmias, myocardial dysfunction, and sudden interruption of right ventricular outflow by pulmonary embolism. Cerebrovascular disease, principally subarachnoid hemorrhage, is less frequently encountered, but equally serious. Toxic and metabolic abnormalities may induce syncope through alterations in blood pressure or cardiac rhythm. Structural cardiac lesions, such as critical aortic stenosis, can also cause sudden loss of consciousness. Dissection of the thoracic aorta rarely manifests primarily as syncope.

**Pivotal Findings**

Most cases of syncope arise from benign causes, so the evaluation is largely focused on identifying those cases caused by serious pathology. The patient’s history, particularly the setting of the syncope (eg, postmicturition, venipuncture), patient position (eg, sitting, standing), prior episodes, and presence or absence of prodromal symptoms, are central to separating benign from serious causes of the syncopal episode. Young, healthy patients with clearly benign syncope, occurring in a compatible setting and preceded by prodromal symptoms, as disclosed by a thorough history, require little more than a physical examination for anemia or other benign exacerbating factors. All other patients require
near-syncope may be perceived as less serious, but mortality appears to be similar. The diagnostic approach to presyncope is therefore the same as for syncope. Additional history regarding the events preceding the syncope is helpful. Occurrence during significant exertion suggests outflow obstruction, whereas occurrence after exercise or prolonged exposure to heat stress suggests orthostasis. The myriad mechanisms that may mediate a neurocardiogenic response, including significant emotional events, micturition, eating, bowel movements, emesis, and movement or manipulation of the neck causing stimulation of the carotid sinus, should be addressed. Occurrence in a supine position or the presence of acute palpitations is relatively specific for syncope of cardiac origin. Seizures may be preceded by an aura and followed by a typical postictal state.

Events during the syncopal episode do not usually clarify the cause. Tonic-clonic movements, related to inadequate cerebral perfusion, can occur in any form of syncope, including benign neurally mediated causes, and should be differentiated from the prolonged activity with subsequent postictal depression of consciousness seen in seizure disorders (see Chapter 92). Trauma from a fall, although important to address, may distract the examiner from evaluating for the underlying syncope that caused the injury.

Further diagnostic evaluation. The yield of an electrocardiogram (ECG) is generally low; however, it is broadly recommended in all other cases (see below) and has the additional advantages of being noninvasive and relatively inexpensive. The clinical examination (history and physical examination) alone can suggest the diagnosis in 45% of cases. For a large portion of the remainder, however, a clear diagnosis for the syncope may not be established in the ED.

Symptoms

Symptoms can often suggest the diagnosis, although the relative weight of the history diminishes in older patients and in those not able to remember clearly the events leading up to the loss of consciousness. The patient is asked to describe the character of the syncopal event. Witnesses may be able to supplement and corroborate the patient’s incomplete recall, and that history should be solicited. Key characteristics include the rate of onset (gradual or abrupt), position on symptom onset (eg, standing, sitting, supine), and duration and rate of recovery. Abrupt onset, occurrence while sitting or supine, and duration of more than a few seconds are usually ascribed to serious, often cardiac, causes of syncope, but firm data are lacking. Similarly, incomplete or

AV, Atrioventricular; CNS, central nervous system.
The postsyncopal events should be queried. Symptoms consistent with a postictal state are characteristic of seizures. Initial vital signs and cardiac monitoring by out-of-hospital medical providers may provide clues to primary cardiac dysrhythmias.

Associated symptoms can offer potentially important clues. Chest pain or dyspnea can suggest myocardial ischemia, aortic dissection, or pulmonary embolism. Diaphoresis and lightheadedness are nonspecific but, if prominent and accompanied by a graying of vision, may suggest orthostasis or neurally mediated causes. Tongue biting and incontinence of urine or stool suggest seizures.

The past medical history is critical in stratifying risk. Congestive heart failure is a key determinant of increased short- and long-term mortality in the setting of syncope. Prior coronary artery or cerebrovascular disease, diabetes, hypertension, and other significant chronic diseases also appear to increase the risk of mortality after syncope.

Certain medications are well established to be associated with syncope (Box 12.2). QT interval–prolonging agents, beta blockers, insulin, and oral hypoglycemics, in particular, deserve attention because of the likelihood of repeated syncope without careful medication monitoring.

**Signs**

The physical examination focuses primarily on the elements affecting the cardiovascular and neurologic systems. Specific findings are detailed in Table 12.1. Signs of orthostasis should be sought in all cases in which this mechanism is suggested. Carotid massage is safe and occasionally revealing; it is indicated in patients for whom the history is suggestive of carotid sinus hypersensitivity. Rectal examination for gross blood or melena is recommended if anemia or gastrointestinal hemorrhage is suspected.

Ancillary Studies

The chief diagnostic adjunct in evaluating syncope is the 12-lead ECG (Table 12.2). It has an overall diagnostic yield of 2% to 9%. In patients younger than 40 years without evidence of cardiovascular disease, the yield is far lower. It is warranted in all cases of syncope except in young, otherwise healthy patients with a clear history and setting for benign, neurally mediated (vasovagal) syncope. Dysrhythmias, preexitation, and a shortened PR or prolonged corrected QT interval may be identified on the 12-lead ECG. Continuous limb lead monitoring of the ECG in the ED may also identify transient dysrhythmias. A right bundle branch block in association with ST elevation in leads V1 through V3 suggests Brugada syndrome. Ischemia or cardiac hypertrophy may be revealed. An ECG showing a right ventricular strain pattern may suggest pulmonary embolism, whereas diffuse ST elevation or electrical alternans helps diagnose pericarditis or pericardial tamponade.

Routine hematologic and urine studies have limited usefulness in the evaluation of syncope and are generally not indicated. When suggested by the history and physical examination findings, however, selective use of the complete blood count, serum electrolyte and glucose levels, urine drug screen, and pregnancy test may identify or exclude some uncommon causes of syncope (see Table 12.2). Chest radiography, bedside pulmonary ultrasound, with or without serum B-type natriuretic peptide (BNP) testing are warranted if heart failure is suspected or known by history. Other than seizure or intracranial hemorrhage, primary neurologic events rarely are the cause of apparent syncope. Cranial computed tomography is indicated only when intracerebral hemorrhage is suspected on the basis of sudden syncope with accompanying headache, particularly of sudden onset, or in the presence of abnormalities on neurologic examination.

In otherwise healthy patients who are reliable historians, in whom a benign dysrhythmia such as episodic supraventricular tachycardia or atrial fibrillation is suspected, outpatient Holter or prolonged event monitoring of the ECG may be helpful. In patients with significant underlying cardiac disease or when a significant dysrhythmia is a possible cause of the syncope, continuous monitoring, echocardiography, or cardiovascular stress testing may be helpful in the inpatient or ED observation unit setting. Depending on the results of the initial evaluation, electrophysiologic studies or coronary artery imaging may be indicated. Electroencephalography is useful only when a seizure episode is suspected. Tilt table testing, although infrequently used in the United States, may have diagnostic value in older patients and children in whom chronic orthostatic hypotension is possible. Orthostatic vital signs, although unreliable in the evaluation of volume status, may be helpful when positional changes are accompanied by typical presyncopal symptoms and a significant rise in heart rate or fall in blood pressure. A schematic of selected diagnostic testing strategies for syncope is depicted in Figure 12.1.

### TESTS USUALLY PERFORMED AS PART OF INPATIENT OR OUTPATIENT EVALUATION

- Prolonged monitoring of the ECG: Dysrhythmia
- Echocardiography: Heart failure, cardiomyopathy, valvular disease
- Exercise and chemical stress ECG: Myocardial ischemia
- Cardiac and coronary artery imaging: Myocardial ischemia
- Electrophysiologic study: Dysrhythmia
- Carotid ultrasound: Stroke, TIA
- Head-up tilt table test: Orthostatic hypotension
- Electroencephalography: Seizures

CT, Computed tomography; ECG, electrocardiogram; β-hCG, human chorionic gonadotropin; MRI, magnetic resonance imaging; TIA, transient ischemic attack.

### DIAGNOSTIC ALGORITHM

The critical diagnoses to consider are listed in Box 12.3. The emergent causes of syncope are protean and are included in Box 12.1. Many other causes, such as neurally mediated and reflex-associated syncope, have benign mechanisms. After stabilization and assessment, the clinical features coupled with onset and recovery can suggest the cause (Table 12.3). A logical approach to the history, physical examination, and diagnostic testing is depicted in Figure 12.2. The emphasis is on risk stratification because the short-term mortality risk in syncope is primarily related to structural cardiac disease, heart failure, and dysrhythmias.

### EMPIRICAL MANAGEMENT

Syncope is by definition a transient event, so most patients are asymptomatic on presentation. Patients with significantly abnormal vital signs, recurrent syncope, or associated symptoms of a concerning nature, such as chest pain, hypotension, abdominal or back pain, or shortness of breath, should undergo rapid evaluation.
CHAPTER 12 Syncope

Multiple guidelines and decision rules have been proposed to aid in risk stratification and, although derivation studies have shown promise, none have performed acceptably in rigorous validation testing. Existing prediction rules should not be strictly applied because they fail to show superior sensitivity, specificity, or prognosis for short-term outcomes when compared to the emergency clinician’s clinical judgment (gestalt). However, prediction rules provide a useful framework for estimating short- and medium-term risk and can inform clinical decision making (Box 12.4).

Hospitalization is required for patients with chest pain, unexplained shortness of breath, history of congestive heart failure, or significant valvular disease. Patients with electrocardiographic evidence of ventricular dysrhythmias, ischemia, significantly prolonged QT interval, or new bundle branch block are also generally admitted. The emergency clinician should consider monitoring patients with any of the following indications: age older than 65 years, preexisting cardiovascular or congenital heart disease, family history of sudden death, serious comorbidities such as diabetes, or exertional syncope.

Patients with critical diagnoses are stabilized in the ED and admitted to the intensive care unit (ICU) or other appropriate inpatient unit. Those with emergent diagnoses are typically admitted to telemetry units or, in selected cases, ED observation units capable of expedited cardiovascular risk stratification strategies, such as a cardiac stress test. Patients with nonemergent diagnoses can be treated as outpatients, generally in a primary care setting.

Box 12.3

Critical Diagnoses to Consider in Syncope

- Myocardial infarction
- Life-threatening dysrhythmias
- Thoracic aortic dissection
- Critical aortic stenosis
- Hypertrophic cardiomyopathy
- Pericardial tamponade
- Abdominal aortic aneurysm
- Massive pulmonary embolism
- Subarachnoid hemorrhage
- Stroke (cerebrovascular accident)
- Toxic-metabolic derangements
- Severe hypovolemia or hemorrhage
- Ruptured ectopic pregnancy
- Sepsis

Multiple guidelines and decision rules have been proposed to aid in risk stratification and, although derivation studies have shown promise, none have performed acceptably in rigorous validation testing. Existing prediction rules should not be strictly applied because they fail to show superior sensitivity, specificity, or prognosis for short-term outcomes when compared to the emergency clinician’s clinical judgment (gestalt). However, prediction rules provide a useful framework for estimating short- and medium-term risk and can inform clinical decision making (Box 12.4).

Hospitalization is required for patients with chest pain, unexplained shortness of breath, history of congestive heart failure, or significant valvular disease. Patients with electrocardiographic evidence of ventricular dysrhythmias, ischemia, significantly prolonged QT interval, or new bundle branch block are also generally admitted. The emergency clinician should consider monitoring patients with any of the following indications: age older than 65 years, preexisting cardiovascular or congenital heart disease, family history of sudden death, serious comorbidities such as diabetes, or exertional syncope.

The ED evaluation of syncope is often inconclusive. After a history, physical examination, and 12-lead ECG, up to 50% of patients do not have a firm diagnosis. A stepwise algorithmic approach can improve diagnostic accuracy. Men younger than 45 years and women younger than 55 years and without worrisome symptoms, signs, or electrocardiographic findings are generally at very low risk for adverse outcome and can be treated on an outpatient basis. The recurrence rate while driving is less than 1%,

<thead>
<tr>
<th>KEY CONCEPTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. The pathophysiology of syncope is dysfunction of both cerebral hemispheres or the brainstem (reticular activating system), usually from acute hypoperfusion. Reduced blood flow may be regional (cerebral vasoconstriction) or systemic (hypotension). Loss of consciousness results in loss of postural tone, with the resulting syncopal episode.</td>
</tr>
<tr>
<td>2. Presyncope (near-syncpe) or lightheadedness are less severe symptoms and may be considered on a continuum with syncope and share causes, mechanisms, and outcomes.</td>
</tr>
<tr>
<td>3. The potential causes of syncope are protean. The first differential diagnostic consideration is to distinguish syncope from other causes of an apparent sudden loss of consciousness, especially seizure and uncommon disorders such as cataplexy.</td>
</tr>
<tr>
<td>4. Most cases of syncope arise from benign causes, so the history is largely focused on identifying those cases caused by serious pathology. The past medical history, particularly cardiovascular disease and heart failure, is a key factor in determining future risk of morbidity and mortality.</td>
</tr>
<tr>
<td>5. The physical examination of syncope focuses primarily on the elements affecting the cardiovascular and neurologic systems.</td>
</tr>
<tr>
<td>6. The chief diagnostic adjunct in evaluating syncope is the 12-lead ECG. It should be obtained on nearly all patients. Studies suggest an overall diagnostic yield of 2% to 9%.</td>
</tr>
<tr>
<td>7. Routine hematologic, chemistry, urine, and imaging studies have limited usefulness in the evaluation of syncope and are generally not indicated unless directed by specific factors in the history or physical examination.</td>
</tr>
<tr>

CHAPTER 12: QUESTIONS AND ANSWERS

12.1. Which of the following statements regarding the epidemiology of syncope is true?

A. Of athletes who die during exercise, 30% have had a prior episode of syncope.

B. People younger than 65 years account for 50% of all patients admitted for syncope from the emergency department.

C. Syncope in adolescents is typically secondary to significant pathology.

D. Syncope in the general population has a prevalence of approximately 1%.

E. Women have an increased risk of recurrence of syncope.

Answer: A. The prevalence of syncope in the general population is approximately 19%. This accounts for 0.8% of emergency department (ED) visits. Approximately 32% of these patients are admitted, and people aged 65 years or older account for 80% of such admissions. Recurrence of syncope may be as high as 50% and is not associated with age or gender. Benign causes of syncope predominate in adolescents and young adults. Approximately 30% of athletes who die during exercise, however, have had a prior episode of syncope as a sentinel event.

12.2. Syncope resulting from serious pathology is usually caused by which of the following?

A. Cerebrovascular disease

B. Dysrhythmias and myocardial ischemia

C. Pulmonary embolism

D. Structural cardiac lesions

E. Toxic-metabolic abnormalities

Answer: B. The principal serious causes of syncope are dysrhythmias and myocardial ischemia. Cerebrovascular disease, principally subarachnoid hemorrhage, is less frequently encountered but equally serious. Toxic-metabolic abnormalities may induce syncope through alterations in blood pressure or cardiac rhythm. Structural cardiac lesions, such as critical aortic stenosis, and sudden interruption of right ventricular outflow by pulmonary embolism, can also cause sudden loss of consciousness.

12.3. Which of the following findings suggest that a patient presenting with syncope can be safely discharged from the ED?

A. Anemia

B. History of congestive heart failure (CHF)

C. Hypotension

D. Normal ECG findings

E. Shortness of breath

Answer: D. A normal electrocardiogram in a patient without other significant risk factors (eg, advanced age, preexisting congestive heart failure, shortness of breath) may be considered for outpatient disposition.
PERSPECTIVE
Coma is defined as a state of profoundly decreased arousal, resembling sleep. Comatose patients exhibit variable reflex behaviors and cannot be aroused with external stimuli. Stuporous or lethargic patients have a decreased level of awareness and also may have a decreased level of consciousness, but these patients can be aroused with external stimuli.

Epidemiology
Depressed consciousness is commonly encountered in daily emergency medicine practice, affecting patients of all ages. Patients may present with a wide spectrum of severity, ranging from sleepiness to frank obtundation. Most cases are the result of a metabolic derangement, usually a glucose disorder or drug overdose or adverse effect, but other common causes include traumatic brain injury, systemic or central nervous system (CNS) infection, ischemic or hemorrhagic stroke, intracranial mass and, rarely, psychiatric illness. Patients with depressed consciousness represent true emergencies because the differential diagnosis includes life-threatening causes that must be rapidly diagnosed and reversed, if possible. An understanding of relevant neuroanatomy and pathophysiology facilitates our understanding of how consciousness is affected in the setting of disease (Fig. 13.1).

Pathophysiology
Consciousness refers to awareness of self and one’s relation to the environment and consists of arousal and awareness. To maintain normal consciousness, the brain requires a constant flow of sensory input and the ability to process this information. Visual, auditory, olfactory, gustatory, visceral, and somatosensory inputs are all synthesized and interpreted by the brain simultaneously. Disruption in this flow of information or inability to process it may lead to depressed consciousness. This may occur at the cortical or subcortical level, and the clinical presentation varies considerably depending on the location of the insult.

Consciousness depends on intact cortical function. The cortex is responsible for the content of consciousness, or awareness. Meanwhile, arousal is initiated by the subcortical structures, including the brainstem nuclei, thalamus, basal forebrain, hypothalamus and, most notably, the ascending reticular activating system (ARAS). ARAS neurons are located predominately in the pons and midbrain, connect to the thalamus, and project to the cortex. Consequently, damage to the dorsal brainstem, thalamus, or axonal projections to the cortex, or extensive injury to bilateral cortices, may result in depressed consciousness or coma.

DIAGNOSTIC APPROACH
Differential Considerations
The differential diagnosis of depressed consciousness and coma is broad (Table 13.1) and potentially involves dysfunction in any area of the brain, from the cortex to the brainstem. It may be the result of a global insult causing massive cortical neuronal dysfunction or a small injury to a critical area of the brainstem responsible for arousal. Most cases have toxic, metabolic, or infectious causes; of these, toxins are the most common. Structural brain diseases account for the remainder of cases. Common, largely reversible causes of depressed consciousness and coma, along with their clinical findings and emergency treatment, are listed in Table 13.1.

Pivotal Findings
Symptoms
A patient with depressed consciousness is unlikely to provide a reliable history. Historical information elicited from alternate sources, such as witnesses, family members, friends, emergency medical services (EMS) personnel, or law enforcement officers, usually guides the diagnostic evaluation. The time course of the patient’s alteration in consciousness should be established. An abrupt onset of coma suggests a stroke, seizure, cardiac event, or poisoning, whereas a more gradual onset of symptoms suggests an infectious process, metabolic disorder, or enlarging intracranial mass. EMS personnel are trained to gather information at the scene and can provide valuable details about the circumstances surrounding the discovery of the patient, such as the presence of empty pill bottles, suicide note, or possibility of environmental exposures.

Family members or caregivers may have information regarding the patient’s recent symptoms, which can offer important diagnostic clues. For example, a preceding, severe, sudden-onset headache suggests an intracranial hemorrhage, cerebral venous sinus thrombosis, or cervical artery dissection, a preceding fever or infection may suggest encephalitis, or a history of depression may
suggest a drug overdose or adverse effects of psychotropic drugs. The patient’s medication history should be carefully reviewed for any recent changes to her or his medication regimen or dosages. A history of taking over-the-counter or alternative medications should also be obtained.

The patient may be carrying additional pieces of information, such as a card in the wallet containing a list of medical conditions and/or medications or a medical alert bracelet or necklace. If the patient can be reliably identified by a family member or photo identification card, the medical record may be accessed for additional medical history. In addition, the patient’s pharmacy may be contacted to obtain an accurate medication list.

Signs

After necessary stabilization measures have been instituted, the patient should be evaluated systematically, starting with an assessment of vital signs, including the oxygen saturation and blood glucose level. An elevated temperature suggests an infection but is also seen in some medical conditions and drug intoxications (eg, salicylates); a lower temperature is seen in environmental exposure but also in medical conditions such as sepsis and hypothyroidism. Hypotension with depressed consciousness indicates shock, with resultant cerebral hypoperfusion. Hypertension may be a sign of intoxication (eg, with cocaine or phencyclidine) or withdrawal (eg, from alcohol or opiates), cerebral or brainstem infarction, subarachnoid hemorrhage, posterior reversible encephalopathy syndrome (PRES), or elevated intracranial pressure (ICP). The combination of hypertension and bradycardia, known as the Cushing reflex, suggests severe elevation in ICP. Bradycardia may also be the result of a myocardial conduction abnormality, cardiac ischemia, or overdose from medications such as beta blockers, calcium channel blockers, cardiac glycosides, or clonidine. Many medical conditions can cause tachycardia and altered mental status, including sepsis, medications with stimulant or anticholinergic effects, severe anemia, hypovolemia, thyrotoxicosis, and acute structural brain injury.

Alterations in respiratory rate, pattern, or depth are usually caused by primary CNS abnormalities and toxic or metabolic disorders. Kussmaul’s breathing consists of deep labored respirations...

Continued
and can be seen in patients with severe metabolic acidosis, particularly diabetic ketoacidosis. Cheyne-Stokes respiration, a cyclic breathing pattern in which episodes of gradually increasing and then decreasing respiratory rate are separated by brief apneic periods, is associated with stroke and heart failure. After an assessment of the patient’s vital signs, a complete head to toe physical examination is performed. The head should be inspected for signs of trauma, such as a scalp laceration or hematoma, periorbital ecchymosis (raccoon eyes), retroauricular ecchymosis (Battle sign), hemotympanum, or cerebrospinal fluid (CSF) otorrhea or rhinorrhea. The hydration of the oral mucous membranes and quantity of salivary secretions provide information regarding the patient’s volume status and may indicate a specific toxidrome. Laceration or contusion of the tongue suggests a recent seizure.

The patient’s cervical spine is immobilized if there is suspicion for a neck injury. The presence of meningismus raises suspicion for meningitis, subarachnoid hemorrhage, and space-occupying CNS lesions. Stridor indicates obstruction of the large airways and is usually caused by infection, anaphylaxis, trauma, or foreign

body aspiration. Goiter in a patient with altered mental status suggests underlying myxedema coma or thyroid storm.

The cardiovascular system is evaluated for rate or rhythm disturbances, murmurs, and signs of volume depletion or overload. Abnormal lung sounds, retractions, and impairments in chest wall excursion indicate a pulmonary cause of depressed consciousness. Examination of the abdomen may reveal ascites or hepatospleno-megaly, suggesting a hepatic cause of coma or a pulsatile mass indicating the presence of an abdominal aortic aneurysm. Bladder distension and decreased bowel sounds suggest an anticholinergic toxidrome. A rectal examination should be performed to assess for gastrointestinal bleeding and retained foreign bodies.

The patient should be fully undressed to evaluate the skin for needle track marks, medication patches, rashes, and/or signs of trauma or infection. The presence of jaundice, palmar erythema, spider angiomata, or caput medusa in a patient with altered mental status should raise concern for hepatic encephalopathy. Petechiae or purpura can be seen in patients with meningococ-cemia, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, or vasculitis. Unusual odors emanating from the patient may provide additional diagnostic clues.

The main objectives of the neurologic examination are to determine the depth of coma, identify lateralizing deficits, and assess for brainstem dysfunction. The examination should proceed systematically and include an evaluation of the patient’s level of consciousness, cranial nerves, brainstem reflexes, and motor responses. The patient’s level of consciousness should be assessed with stimuli of increasing intensity. Auditory stimuli, such as a verbal cue or loud noise, may be used first. If the patient does not exhibit a response to auditory stimuli, noxious stimuli may be applied, such as a sternal rub, nail bed compression, or pressure on the medial aspect of the supraorbital ridge or posterior aspect of the mandibular ramus.

Level of consciousness may also be evaluated using a coma scale. The two most widely used scales are the Glasgow Coma Scale (GCS; Table 13.2) and Full Outline of UnResponsiveness (FOUR) score (Table 13.3). Although originally developed for patients with traumatic brain injury, the GCS is commonly applied to all patients presenting with altered mental status. The GCS has considerable limitations because it does not account for abnormalities in brainstem function and may not detect subtle changes in the neurologic examination. The FOUR score has been validated in a variety of clinical settings and has higher interrater reliability than the GCS. The FOUR score incorporates a more detailed assessment of brainstem reflexes and has greater predictive value than the GCS in intubated patients and those with very low GCS scores. The utility of both coma scales can be max-imized by reporting the scores of each element and total score.

The cranial nerves are tested, with particular attention paid to the eyes. The size, reactivity, and symmetry of the pupils can provide important diagnostic clues. Pinpoint pupils that are minimally reactive or unreactive to light may be a result of damage to the pons, usually from hemorrhage or infarction. Papillary dilation with loss of pupillary reactivity in a comatose patient should raise concern for an expanding intracranial mass with transtentorial herniation, resulting in compression of the oculomotor nerve or injury to the midbrain. Drugs and other toxins can also cause miosis (eg, opioids, clonidine, organophosphates) or mydriasis (eg, amphetamines, tricyclic antidepressants). Fixed, mid-size pupils can be seen in severe midbrain injury and may be the first sign of brain death.

Eye position and movement are also noted. Forced deviation of the eyes, usually in the horizontal plane, may indicate an ipsilateral hemispheric or contralateral pontine lesion. Seizures can also cause horizontal eye deviation, typically away from the cerebral lobe containing the seizure focus. Horizontal disconjugate gaze can be seen in patients who are sedated, drowsy, or intox-

The corneal reflex is tested by gently touching the edge of the cornea with a wisp of cotton and observing for blinking of the eyes. The gag reflex is elicited by stimulating the posterior pharynx and observing for brisk elevation of the soft palate and bilateral contraction of the pharyngeal muscles. Because the gag reflex is symmetrically diminished or absent in a subset of normal individuals, the test is most informative when the response is asymmetric.

Motor function is assessed by observing any spontaneous movements and testing the motor responses to verbal commands and noxious stimuli. Purposeful movements should be distinguished from reflex activity. Examples of purposeful movements include following commands and localization of or withdrawal from painful stimuli. Reflexive responses include decorticate posturing, characterized by adduction of the shoulders and flexion of the elbows, wrists, and fingers, and decerebrate posturing, which consists of shoulder adduction, elbow extension, and forearm pronation. Although usually associated with focal brain lesions, posturing reflexes can also be seen in systemic conditions affecting the CNS, such as toxic and metabolic disorders.

Muscle tone, assessed by passive manipulation of the extremities, is usually decreased in structural brain disease but not affected in most metabolic conditions. Generalized muscle rigidity occurs in patients with neuroleptic malignant syndrome and malignant hyperthermia. Myoclonus may be a sign of NCSE, hepatic or renal dysfunction, or hypercarbic respiratory failure.

Ancillary Testing

Laboratory evaluation of a patient with depressed consciousness should begin with point of care measurement of the serum glucose level to confirm or exclude hypoglycemia. A comprehensive metabolic panel should be carried out to identify metabolic acidosis, renal or hepatic dysfunction, and any electrolyte derangements, such as hyponatremia or hypercalcemia. In a patient with metabolic acidosis, a widened anion gap suggests possible ketoacidosis (eg, from diabetes, alcohol ketoacidosis, starvation), lactic acidosis (eg, from sepsis, hypoperfusion, cyanide poisoning), uremia, or intoxication (eg, with methanol, ethylene glycol, salicylates). Anion gap in the context of poisoning is discussed in Chapter 139. A complete blood count may reveal profound anemia or thrombocytopenia, but this would not account for the depressed mental status, unless as a cause of intracranial hemorrhage or severe hypotension. Although an elevated white blood cell count can be a marker of infection, it is nonspecific and rarely helpful in discerning the cause of altered mental status. An abnormally low white blood cell count, however, suggests an immunocompromised state and should raise suspicion for infection or malignancy. An elevated prothrombin or partial thromboplastin time can be seen in blood dyscrasias, liver disease, and anticoagulant use.

Urinalysis can provide valuable diagnostic information. A high urine specific gravity suggests dehydration. Glucosuria can be seen in diabetic ketoacidosis and hyperosmolar hyperglycemic state. Detection of white blood cells, leukocyte esterase, and nitrites in the urine indicates a urinary tract infection. The presence of calcium oxalate crystals is associated with ethylene glycol ingestion.

Serum salicylate and acetaminophen levels should be determined if toxicity is suspected, such as a case of an unexplained anion gap acidosis or hepatic failure. Other toxicologic tests, such as the serum ethanol level and urine drug screen, are unlikely to significantly affect the acute management of a patient with depressed consciousness. Blood gas analysis can be used to rapidly assess acid-base balance and identify hypoxia or hypercarbia. Co-oximetry should be included if carbon monoxide poisoning or methemoglobinemia is suspected. Due to its poor sensitivity and specificity, the serum ammonia level has little utility in the evaluation of altered mental status. Ammonia concentrations can be elevated in a variety of nonhepatic conditions, such as valproic acid toxicity and inborn errors of metabolism, and can be normal.
in patients with hepatic encephalopathy. Thyroid function studies can help confirm myxedema coma or thyrotoxicosis. Blood and urine cultures should be tested if there is concern for infection. CSF analysis should be undertaken if CNS pathology such as infection or hemorrhage is suspected. Neuroimaging should be performed prior to lumbar puncture to exclude an intracranial mass lesion.

Noncontrast computed tomography (CT) of the brain, because of its wide availability and rapid acquisition, is the imaging modality of choice for the initial evaluation of a patient with depressed consciousness. It should be obtained in patients with preceding head trauma, those with suspected structural brain disease, and those in whom the diagnosis is not identified by other means. Noncontrast cranial CT may identify intracranial hemorrhage, hydrocephalus, cerebral edema, or mass lesion, and may reveal signs of ischemic stroke or elevated ICP. CT angiography (CTA) of the head and neck should be performed if brainstem dysfunction is suspected on neurologic examination. It can provide valuable information regarding the cerebral vasculature and aid in the diagnosis of an intracranial aneurysm, arteriovenous malformation, cerebral venous thrombosis, and basilar or vertebral artery stenosis or occlusion.

Due to bone artifact, CT has limited utility in the visualization of the posterior fossa. In comparison, magnetic resonance imaging (MRI) of the brain is better for identifying structural lesions in this region. MRI also provides greater anatomic differentiation of cortical and brainstem structures and is superior to CT for detecting early ischemic stroke, visualizing the arterial system, and identifying infectious, inflammatory, and neoplastic processes. However, MRI is less practical than CT because of cost, accessibility, and the length of time needed to acquire each study, which limits the ability to monitor and access a critically ill patient.

Chest radiography may identify pneumonia, pneumothorax, tumor, or foreign body, and may reveal signs of aortic dissection or congestive heart failure.

An electrocardiogram may diagnose cardiac ischemia, a conduction block, or an arrhythmia. It may also provide supporting evidence for an electrolyte abnormality (potassium or calcium), a drug ingestion (tricyclic antidepressant), hypothermia, or structural brain injury.

Electroencephalography (EEG) should be performed to evaluate for NCSE, which can manifest de novo and present with coma or persist after cessation of convulsive seizures. An EEG is also indicated in seizure patients who have received sedative or paralytic medications to assess for ongoing seizure activity. See Chapter 92.

### Diagnostic Algorithm

Critical and emergent diagnoses that require immediate consideration, evaluation, and treatment are listed in Table 13.1. Information from the history, physical examination, and initial battery of tests guides the direction of imaging and additional testing. Neuroimaging is performed next, but not before treating emergent causes, such as hypoglycemia or opioid toxicity. An algorithmic approach to the diagnosis and management of patients with depressed consciousness is presented in Fig. 13.2. This approach allows diagnostic assessment and therapeutic intervention to proceed in parallel.

### Empirical Management

The management of comatose patients should begin immediately on arrival, before a definitive diagnosis is established. Management prioritizes oxygenation and perfusion while the diagnostic evaluation is initiated. A complete set of vital signs, including pulse oximetry, should be obtained. Care should be taken to avoid hypoxia and hyperoxia because both are deleterious. A goal oxygen saturation of 96% is acceptable and avoids both extremes. Invasive (IV) access is established and cardiac monitoring initiated. A rapid bedside glucose level is determined and hypoglycemia treated immediately. Rapid treatment of hypoglycemia will lead to reversal of coma due to neuroglycopenia. An empirical trial of naloxone will lead to rapid reversal of opioid toxicity, as well as several other medication overdoses (see Chapter 156). We recommend administering an initial naloxone dose, 0.4 mg IV, and increasing up to 10 mg IV if necessary. Effective reversal with naloxone may obviate the need for endotracheal intubation in these patients. In cachectic malnourished patients, women with severe hyperemesis gravidarum, alcoholics, or other patients with suspected thiamine deficiency, empirical administration of thiamine 100 mg IV is recommended.

If initial management efforts do not promptly result in improvement, the patient’s ability to protect and maintain a patent airway should be reassessed. Failure to oxygenate, ventilate, or protect the airway are indications for intubation. GCS scores inversely correlate with aspiration risk, but GCS alone does not accurately predict which patients will maintain protective airway reflexes. Patients with a GCS score higher than 8 cannot be considered safe or not at risk for aspiration. Consider the history, examination, and ability of future providers caring for a patient to perform an airway intervention successfully, should it become necessary, when making the decision to intubate or not. We recommend endotracheal intubation in most patients with coma and a GCS score of 8 or lower and for any patient thought not to be capable of sustained airway self-maintenance and protection.

Prior to intubation, a detailed neurologic examination is performed, with particular attention to assessing brainstem function. Once the airway has been reassessed and secured as needed, we recommend treating patients with undifferentiated coma and clinical suspicion for meningitis (ie, fever, other signs of infection, sepsis, rash) empirically with ceftriaxone, 2000 mg IV, prior to CT imaging. Additional antibiotics such as vancomycin may be added if local pneumococcal resistance rates are high, an indwelling venous catheter is present, or a hospital-acquired pathogen is suspected. If encephalitis is suspected, empirical acyclovir, 800 mg IV, is recommended.

If the head CT or CTA is diagnostic, notify the appropriate consultant (neurosurgery or neurology) and arrange for definitive management. In all patients with brain injury of any type, especially those with signs of herniation, general principles of neuroprotective care are recommended (Box 13.1; see Chapter 7).

If the head CT or CTA is nondiagnostic, determine if there are any other emergent conditions that could be treated and potentially reversed. The differential diagnosis is listed in Fig. 13.2 and may be easily recalled using the mnemonic shown.

Once the initial diagnostic evaluation has been completed and initial management is underway, most patients will require definitive treatment in an intensive care unit. The disposition will

### Box 13.1

**Principles of Neuroprotective Resuscitation**

- Elevate head of bed to 30° if there is no suspicion for thoracic spine injury.
- Avoid constricting ties or collars around neck.
- Avoid hypoxia and hyperoxia.
- Maintain end-tidal CO₂ at 35 cm H₂O.
- Avoid hypotension.
- Avoid hyperthermia.
- Prevent and treat seizure activity.

CO₂, Carbon dioxide; H₂O, water.
Patients treated and stabilized in the emergency department and some may be safely discharged home after a period of observation. Patients with alcohol or recreational drug intoxication and no other discernible cause of depressed consciousness may be discharged when clinically sober. Most patients, even if the level of consciousness markedly improves with initial treatment, will require admission to the hospital or observation unit.

Depend on what is discovered during the evaluation. Patients found to have a structural abnormality on imaging potentially requiring neurosurgical intervention must be rapidly transferred to a facility with neurosurgical capabilities if not available at the initial location.

Many patients with toxic or metabolic causes (e.g., opioid overdose, hypoglycemia) of depressed consciousness may be rapidly treated and stabilized in the emergency department and some may be safely discharged home after a period of observation. Patients with alcohol or recreational drug intoxication and no other discernible cause of depressed consciousness may be discharged when clinically sober. Most patients, even if the level of consciousness markedly improves with initial treatment, will require admission to the hospital or observation unit.

**KEY CONCEPTS**

- Consciousness consists of arousal (subcortical) and awareness (cortical).
- Damage to the dorsal brainstem, thalamus, or axonal projections to the cortex, or extensive injury to bilateral cortices, may result in depressed consciousness or coma.
- Toxic, metabolic, and infectious causes of coma make up 65% of cases; of these, toxins are the most common. Structural brain diseases make up most of the remaining 35% of cases.
- An abrupt onset of coma suggests a stroke, seizure, cardiac event, or poisoning.
KEY CONCEPTS—cont’d

- A patient with depressed consciousness is unlikely to provide a reliable history. Historical information should be elicited from other available sources, such as EMS and family.
- The neurologic examination includes an evaluation of level of consciousness, cranial nerves, brainstem reflexes, and motor responses.
- Pinpoint pupils may represent a pontine infarct or intoxication from opioids, clonidine, or cholinergic medications.
- Hypoglycemia and hypoxia are two easily identified and reversible causes of coma.

- An empirical trial of naloxone will lead to rapid reversal of opioid toxicity and other medication overdoses.
- Nonconvulsive status epilepticus should be suspected in cases of coma of undetermined cause and is diagnosed by EEG.
- Most patients with coma will require intensive care. Transfer patients if the cause of coma is not treatable in the current facility (eg, structural lesion requiring neurosurgery).

CHAPTER 13: QUESTIONS & ANSWERS

13-1. In infants, what is the most common cause of a depressed level of consciousness?
   A. Accidental toxic ingestion
   B. Hypoxia
   C. Infection
   D. Inborn errors of metabolism
   E. Physical abuse

   **Answer:** C. Causes of a depressed level of consciousness vary with patient age. In infants, infectious causes of depressed consciousness are most common; however, trauma secondary to physical abuse and metabolic derangements from inborn errors of metabolism can be seen. Accidental toxic ingestions are often seen in younger children but are very uncommon in infants. Young adults and adolescents are more likely to present after recreational drug use or trauma. Finally, older adults are particularly vulnerable to infectious causes, medication changes, and alterations in their living environments.

13-2. What Glasgow Coma Scale (GCS) score would be given to an adult patient who opens the eyes to painful stimuli, speaks in incomprehensible words, and 4 points for withdrawing to painful stimuli?
   A. 6
   B. 7
   C. 8
   D. 9
   E. 10

   **Answer:** C. Using the GCS, this patient would receive 2 points for eye opening to pain, 3 points for persistently being irritable, and 3 points for flexion to painful stimuli.

13-3. What GCS score would be given to a pediatric patient who opens the eyes and flexes the extremities to painful stimuli and who is persistently irritable?
   A. 6
   B. 7
   C. 8
   D. 9
   E. 10

   **Answer:** C. Using the GCS, this patient would receive 2 points for eye opening to pain, 3 points for persistently being irritable, and 3 points for flexion to painful stimuli.

13-4. Awareness of one's self or surroundings defines which of the following?
   A. Cognition
   B. Consciousness
   C. Judgment
   D. Memory
   E. Orientation

   **Answer:** B. Consciousness is defined as the awareness of one's self or surroundings; it is made up of arousal and cognition. Cognition is the combination of orientation, the accurate perception of what is experienced, judgment, the ability to process input data to generate more meaningful information, and memory, the ability to store and retrieve information.
CHAPTER 14
Confusion

J. Stephen Huff

PERSPECTIVE

The term confusion connotes an acute alteration in higher cerebral functions, such as memory, attention, or awareness. The ability to sustain and focus attention is impaired. Confusion is a symptom, not a diagnosis. The degree of confusion may fluctuate, as may the patient’s level of consciousness. Implicit in the definition is a recent change in behavior. Chronic confusion may not be present in some of the same pathophysiologic processes causing confusion and are discussed in Chapter 13. Confusion may range in severity from a mild disturbance of short-term memory to a global inability to relate to the environment and process sensory input. This extreme state is termed delirium (see Chapter 94).

Confusion has many causes, and an orderly approach is necessary to discover the causative diagnosis. The assessment of mental status and cognitive impairment in older emergency department (ED) patients is an important part of their evaluation and has been proposed as a key quality indicator by the Society for Academic Emergency Medicine Geriatric Task Force. The absence of a chief complaint of altered mental status should not reassure the emergency clinician that an acute mental status change is absent. History from family or caregivers, structured physical examination, and use of a specific assessment tool may be needed to detect the presence of confusion.

Epidemiology

Physicians underestimate the incidence of confusion in patients. Confusion is often accepted as an incidental or secondary component of another condition. A patient with injuries from a motor vehicle crash or with dyspnea may be confused, but the primary condition overshadows the underlying abnormal mental status. When confusion exists as an isolated or unexplained finding, it is more likely to receive full and immediate consideration by the emergency clinician. Confusion is estimated to be present in 2% of ED patients, 10% of all hospitalized patients, and 50% of older hospitalized patients. Delirium in older ED patients is an independent predictor of increased mortality within 6 months.

Pathophysiology

Conceptually, consciousness is divided into elements of alertness or arousal and elements constituting the content of consciousness. Confusion is largely a problem of the content portion of consciousness. Any underlying clinical process that disrupts optimal central nervous system (CNS) functioning can result in confusion. Global CNS dysfunction usually results from substrate deficiencies (eg, hypoglycemia, hypoxemia), neurotransmitter dysfunction, presence of, or withdrawal from a CNS drug or toxin, or circulatory dysfunction. Sepsis syndrome is also associated with encephalopathy. Compounding this problem is the concept that the reserve of cognitive function varies from individual to individual; individuals with a preexisting impairment may become confused after even minor changes in their normal physiologic state.

DIAGNOSTIC APPROACH

Differential Considerations

Certain critical and emergent diagnoses require prompt recognition (Box 14.1). Four groups of disorders encompass most causes of confusion: (1) systemic diseases secondarily affecting the CNS; (2) primary intracranial disease; (3) exogenous toxins; and (4) drug withdrawal states (Box 14.2).

In general, schizophrenia and other psychiatric disorders do not present with confusion and cognition, including orientation and attention, are normal in these patients unless psychosis or agitation is severe (see Chapter 100). The term psychosis implies a disorder of reality testing and thought organization severe enough to interfere with normal daily functioning. Psychosis is a nonspecific syndrome, and careful evaluation is required to differentiate between psychiatric and medical origins (eg, drug intoxication, other systemic process; Table 14.1).

Focal cortical dysfunction, such as from tumor or stroke, typically does not cause confusion although, occasionally, receptive or expressive dysphasia may be mistaken for confusion. Occasionally, other focal neurologic abnormalities may mimic a confusional state. A person with a new visual field deficit and visual neglect from stroke or intracranial mass may have difficulty ambulating in familiar surroundings and may be labeled as confused, but this reflects focal neurologic injury and not a confusional state from global CNS dysfunction. Frontal lobe dysfunction from stroke, subdural hematoma, or tumor may result in personality changes and the report of confusion by family or friends. Careful assessment of mental status assists in resolving the diagnostic dilemma.

Likewise, subcortical or brainstem dysfunction usually results in a diminished level of alertness and consciousness, not confusion. A person with a new visual field deficit and visual neglect may have difficulty ambulating in familiar surroundings and may be labeled as confused but, in this case, it reflects a focal neurologic injury. Frontal lobe dysfunction from stroke, subdural hematoma, or tumor may result in a change in personality that may be reported as confusion by family or friends.

Pivotal Findings

A patient with confusion is evaluated through a focused history, physical examination, and rapid bedside screening assessment tools. Response to specific therapies (eg, dextrose, naloxone) may identify critical causes. Additional evaluation may include laboratory testing and diagnostic imaging, which are usually confirmatory of one of a number of suspected conditions. Examples of pivotal historical findings that provide the key to the diagnosis include new medications, preceding infection, history of head trauma, history of seizures, and time course of symptom onset. Examples of pivotal physical findings include altered vital signs, evidence of head trauma, focal neurologic deficits, loss of
### Critical and Emergent Diagnoses

**CRITICAL**
- Failure to oxygenate
- Failure to ventilate
- Hypoglycemia
- Elevated intracranial pressure with impending herniation

**EMERGENT**
- Systemic diseases
  - Electrolyte and fluid disturbance
  - Endocrine disease—thyroid, adrenal

*Note:* These represent a partial diagnosis; causes are myriad. "Critical" in this case means conditions that need immediate assessment and correction within moments, such as oxygenation and ventilation problems or hypoglycemia. Because confusion represents central nervous system failure, other problems may be considered critical as well and may necessitate intensive care unit admission, depending on their severity.

### Major Categories: Differential Considerations

- Primary intracranial disease
- Systemic diseases secondarily affecting the central nervous system
- Exogenous toxins
- Drug withdrawal

### Findings to Help Differentiate Between Organic and Functional Causes of Confusion

attention, preservation of orientation, and presence of a toxic syndrome (so-called toxidrome).

**Symptoms**

Confusion is frequently reported by caregivers and family members rather than by the patient. Families may articulate the complaint as confusion but also may describe rambling, disorientation, speaking to persons not there, patient’s inability to find his or her way around familiar surroundings, or simply “not being right.” An essential goal of the history is to determine when the patient last exhibited normal thinking and behavior and what normal is for the particular patient.

The initial task in evaluating the patient is to define the symptoms and severity of confusion. The specific behaviors that are of concern to the patient or caregivers should be delineated. Often, the family is the most valuable source for information; a physician or other caregiver with an established relationship with the patient also may be helpful. The duration of the confusion, recent changes in medications, and recent illnesses are important points in the clinical history. Hallucinations are not unique to psychiatric illness and can commonly occur in confusion states, especially delirium. Hallucinations in delirium tend to be visual, with or without auditory components, powerful, fleeting, and poorly organized. A history of medication or substance abuse and any recent changes, especially cessation of benzodiazepines or ethanol, should be sought.

### Signs

The general physical examination may suggest a cause of confusion or altered mental status, such as congestive heart failure, pneumonia, or signs of illicit drug use. Fever suggests an infection as the cause of altered mental status and should prompt a search for the source, particularly urinary tract infection in the older patient. New focal neurologic findings suggest a possible mass lesion or stroke, but these would manifest with confusion only if global cortical dysfunction were caused by surrounding cerebral edema or elevated intracranial pressure by severe mass effect. Aphasia, fluent or nonfluent, is a focal sign suggesting a lesion in the dominant cerebral hemisphere. In confusional states, speech may be abnormal and is often incoherent, and the rate of speech may be rapid or slowed.

Identification of the elements of a toxidrome, such as serotonin syndrome, may assist in the identification of a drug effect as the cause of confusion prompting intervention or consultation. A careful inspection of the skin, especially in dependent areas such as the buttocks, may reveal a culprit skin infection. In some patients, confusion may be subtle, and an informal assessment of mental status and cognitive abilities may fail to detect abnormalities. Emergency clinicians often fail to perform a formal assessment for confusion or delirium, although studies have shown that delirium in older adults often goes unrecognized unless a structured assessment is performed. Casual conversation and basic questions about orientation will not detect confusion or delirium in all patients. A simple screening test is needed that goes beyond simple orientation and the apparent ability to carry on a normal conversation.

Attention deficit is the common denominator in confusional states. Patients with normal attention function should be able to perform digit repetition forward (five or six digits) and backward (four digits). Additionally, spelling a commonly used word backward (“world” is frequently used) or listing the months of the year in reverse order is an accurate screening test.**3,4** We recommend answering orientation questions, performing forward and backward digit repetition, and reciting the months of the year in reverse order as a brief screening examination.

The tools traditionally used by consultants for assessing cognitive impairment or dementia such as the Mini-Mental State Examination (MMSE) will show low performance in confused patients because an ability to sustain attention is required for these tasks. The MMSE (Fig. 14.1) was created as a screening instrument for cognitive impairment such as dementia, and many test items require focus and attention. If additional testing is performed in...
There are other simple tests that have been proposed for screening for delirium in older patients. The geriatric emergency department guidelines recently approved by emergency medicine and geriatric professional societies recommend a two-step approach. First, an assessment known to be sensitive in detecting delirium is recommended to be performed by ED personnel (Fig. 14.3). The delirium triage screen assesses level of consciousness by observation and assesses attention by a simple question (backward spelling of five-letter word). If this triage screen is positive, a

Final score is sum of the totals; score less than 15 suggests the presence of altered cognition and need for further assessment.

**Fig. 14.3.** Delirium triage screen. bCAM, Brief confusion assessment method. (Modified from American College of Emergency Physicians; American Geriatrics Society; Emergency Nurses Association; Society for Academic Emergency Medicine; Geriatric Emergency Department Guidelines Task Force: Geriatric emergency department guidelines. Ann Emerg Med 2014;63:e7–e25.)
more specific evaluation is recommended. The guidelines recommend a modification of the confusion assessment method, termed the brief confusion assessment method (bCAM) as a second test. This assesses four features—mental status by history or examination, further assessments of attention, level of consciousness, and orderly thinking (Fig. 14.4).

Ancillary Testing

Synthesis of information from the history and physical examination guide the emergency clinician in the choice of laboratory tests most likely to yield valuable diagnostic information. Pulse oximetry may reveal hypoxia or bedside glucose testing may reveal hypoglycemia or hyperglycemia. In the presence of fever, chest radiography and urinalysis often reveal the source of the infection causing the altered mentation. In older patients, urinalysis should guide the emergency clinician in the choice of laboratory tests most likely to yield valuable diagnostic information. Pulse oximetry is not reliable.

If common and simple tests do not identify a cause, advanced diagnostic testing may be indicated. The clinical situation and overall condition of the patient determine the speed and direction of evaluation and whether the tests are obtained in the ED. Additional laboratory work is often of decreasing yield but serum ammonia and calcium levels and selected drug and toxicologic testing may be ordered in this second tier of evaluation. Blood and urine cultures are obtained in the febrile patient when hospital admission is anticipated and a clear infectious source is not evident. Paracentesis or thoracentesis may be appropriate if ascites or a new pleural effusion is present.

Cranial computed tomography (CT) scanning is often done to screen for CNS lesions in the absence of another identified source of the confusion. Unanticipated abnormalities are uncommonly found, although focal findings on examination increase the yield of neuroimaging.

Lumbar puncture may allow discovery or exclusion of CNS infection if no other source has been identified. Cerebrospinal fluid examination may clarify a diagnosis of meningitis, encephalitis, or subarachnoid hemorrhage.

If the cause of confusion remains unclear, or if the patient is unable to function safely in their current environment, admission is recommended for observation, and additional evaluation with consideration of obtaining magnetic resonance imaging or electroencephalography.

DIAGNOSTIC ALGORITHM

Certain critical and emergent diagnoses require prompt recognition for morbidity or mortality to be prevented (Box 14.1). The diagnosis of confusion implies the exclusion of other states of altered mental status, such as a decompensated psychiatric syndrome (Fig. 14.5).

The first step in assessing a patient with confusion is to ensure that the critical reversible causes are identified and addressed (eg, hypoglycemia, hypercarbia, hypoglycemia; Fig. 14.6). A complete set of vital signs, including temperature and oxyhemoglobin saturation, and a bedside blood glucose level should be determined promptly. Next, an assessment for delirium is performed using the confusion assessment method (CAM) score. If delirium is suspected, the fluid examination may clarify a diagnosis of meningitis, encephalitis, or subarachnoid hemorrhage.

If the patient’s CAM score is negative, a more specific evaluation is recommended. The guidelines recommend a modification of the confusion assessment method, termed the brief confusion assessment method (bCAM) as a second test. This assesses four features—mental status by history or examination, further assessments of attention, level of consciousness, and orderly thinking (Fig. 14.4).
If the cause of confusion remains uncertain, admission to an inpatient or observation unit is considered for further evaluation. Ideally, care is promptly coordinated with consultants and admitting physicians.

**EMPIRICAL MANAGEMENT**

Oral or intravenous glucose therapy is indicated if an abnormally low blood glucose level is discovered. In adults, 25 g dextrose (50 mL of 50% dextrose) is commonly administered, and the bedside glucose level is checked again. Thiamine, 100 mg IV, is recommended at the time of dextrose administration. Hypoxia and hypocapnia are addressed with noninvasive or invasive strategies tailored to the patient's presentation. If a toxidrome is present, treatment is directed toward the specific toxin or syndrome.
Confused or agitated patients should be protected from harming themselves or others. Close observation may need to be supplemented by medications or physical restraint. Family members may offer valuable assistance in observing and comforting the patient. Environmental manipulations such as dim lighting or providing a quiet environment may be helpful. Confinement or physical restraint may be necessary at times but should be used with careful adherence to institutional guidelines. Benzodiazepines, butyrophenones, or newer antipsychotic medications may be used if necessary to decrease agitation, but any of these might confound evaluation of the confusional state. No studies allow precise recommendation but in adults we recommend midazolam, titrated beginning with 1 to 2 mg IV or 5 mg IM.

**KEY CONCEPTS**

- Confusion is a symptom, not a diagnosis.
- Focal cortical dysfunction, such as from tumor or stroke, typically does not cause confusion.
- Any underlying clinical process that disrupts optimal central nervous system (CNS) functioning can result in confusion.
- Emergent causes of confusion that need immediate detection and treatment include hypoglycemia, hypoxemia, hypotension, sepsis, and toxic ingestions.
- Assessment of attention is fundamental for the assessment of patients with confusion.
- The confusion assessment method (CAM) is a validated tool for identifying patient with delirium.
- Delirium often goes unrecognized unless a structured assessment tool is used.
- Midazolam is useful for managing undifferentiated agitation while the diagnostic evaluation is in progress.

Age-appropriate antibiotic treatment for coverage of causes of sepsis tailored to the patient’s comorbidities may be considered in ill febrile patients while a definitive evaluation is in progress. If a CNS infection is suspected, age-guided empirical antibiotic treatment without delay for lumbar puncture is recommended (see Chapter 99).

In patients with a prolonged postictal period or who are suspected of being in nonconvulsive status epilepticus, empirical treatment with lorazepam, 1 mg IV, up to a maximum of 10 mg, may be considered pending consultation and additional testing (see also Chapters 15 and 92).

CHAPTER 14: QUESTIONS & ANSWERS

14.1. A 70-year-old man with a chief complaint of confusion is brought to the emergency department by his family. Which of the following initial assessments should be included?
   A. All of these
   B. Blood pressure
   C. Pulse oximetry
   D. Rapid bedside glucose testing
   E. Temperature

   Answer: A. Confusion may result from shock states, hypoglycemia, and hypoxia. Evaluation for these conditions is a priority. Confusion is a symptom rather than a medical condition, and reversible remedial causes should be investigated.

14.2. A variety of screening tests may aid in the detection of confusion. Which of the following conditions may inhibit performance of these tests?
   A. Attention impairment
   B. Cortical blindness
   C. Disorientation
   D. Hemiparesis
   E. Long-term memory impairment

   Answer: A. Deficiency in attention span will impair performance of all tests of cognitive performance. If the patient cannot attend to simple tasks, more detailed testing is not possible.

14.3. A 30-year-old patient is brought to the emergency department for evaluation of odd behavior. Which of the following characteristics might suggest a psychiatric cause for the behavior?
   A. Auditory hallucinations
   B. Disorientation
   C. Fever
   D. Olfactory hallucinations
   E. Visual hallucinations

   Answer: A. Auditory hallucinations are common in psychiatric illness. If hallucinations are present in organic causes of delirium, they are usually visual, tactile, or olfactory. Orientation is generally preserved with primary psychiatric disorders unless psychosis or severe impairment is present.

14.4. Postictal confusion is common in patients with seizures, but if improvement in consciousness does not occur within 20 to 30 minutes after seizure cessation, which of the following conditions should be considered?
   A. all of these
   B. electrolyte abnormalities
   C. head injury
   D. hypoglycemia
   E. nonconvulsive or subtle status epilepticus

   Answer: A. For a patient with a generalized convulsive seizure, termination of the seizure activity should be followed by improvement of mental status within a short period of time. For the patient with persistently altered consciousness or prolonged confusion, consider causes of provoked seizures with prolonged altered mental status or persistence of subtle seizures.
Seizures are episodes of abnormal neuronal excitation and are generally a manifestation of an underlying process. The goal of the emergency clinician is to differentiate a seizure from a nonseizure, unprovoked and not linked to an inciting event. Secondary seizures are often self-limiting but, if sustained, require prompt treatment to minimize complications. Nonconvulsive seizure activity and nonconvulsive status epilepticus may be relatively obscure in their presentation and should be suspected in patients with altered behavior or coma of undetermined cause.

Epidemiology

More than 10% of the US population will experience at least one seizure during their lifetime; however, only 3% will be diagnosed with epilepsy. Alcohol and other intoxications and central nervous system pathologies, such as tumor, stroke, trauma, or infection, are common causes of seizures in adults.

Seizures are classified based on cause (primary or secondary), effect on mentation, and motor activity. Primary seizures are unprovoked and not linked to an inciting event. Secondary seizures may be caused by trauma, illness, intoxications and poisonings, metabolic disturbances, and cerebral tumors. A generalized seizure is defined as abnormal neuronal activity in both cerebral hemispheres, which results in an alteration in the level of consciousness. Generalized seizures may be further divided into tonic-clonic, absence, atonic, and myoclonic. Focal seizures usually involve one cerebral hemisphere, thereby preserving consciousness, although these seizures may progress and cause an altered sensorium. Some seizures are impossible to classify because of an inadequate or inaccurate description of the ictal activity.

Convulsive seizures are characterized by uncontrolled, rhythmic motor movements and can affect part or all of the body. Patients with nonconvulsive seizures may manifest automatisms, confusion, altered mental status, abnormal behavior, or coma.

Status epilepticus has actually experienced a seizure. Once a seizure is suspected, the patient—including loss of driving privileges and exposure to potentially toxic medicines—the first diagnostic task in the emergency department (ED) is to determine whether the patient has actually experienced a seizure. Once a seizure is suspected, there must be a search for underlying precipitants. New-onset seizures or a change in seizure patterns in epileptics may be the primary manifestation of serious underlying diseases, and should prompt a focused evaluation. The differential diagnoses to consider when evaluating for seizure are listed in Box 15.2. Neurogenic seizures must be differentiated from seizure mimics, which include syncope, dysrhythmia, migraine, decerebrate posturing from increased intracranial pressure, dystonic drug reactions, tetanus, strychnine poisoning, and psychogenic events.

Syncope, including simple vasovagal syncope, can be associated with occasional twitching movements or even a brief, more generalized convulsion, which can be misdiagnosed as a seizure. This is referred to as convulsive syncope. Myoclonic activity is brief (usually a few seconds) and recovery is as for any other syncopal event, without any postictal altered mental status or confusion. Generalized, sustained (more than a few seconds) tonic-clonic movements, tongue biting, or postictal amnesia are rare with convulsive syncope, and should be presumed to represent a nonsyncopal generalized seizure. When put in the context of when and where the event occurred, the duration of the event,
type of movements, and presence or absence of a postictal state, convulsive syncope usually is easily differentiated from seizure. Migraine with an aura can be confused with nonconvulsive seizures. This is compounded by the finding that many migraine patients have abnormal electroencephalograms (EEGs). Basilar migraine can result in loss of consciousness, making the differentiation even more difficult. These patients will almost always have a history of migraine, often with similar presentation. When the event is the first that the patient has experienced, differentiation can be difficult, and the event should be presumed to be a seizure until this has been excluded by further evaluation and testing.

Psychogenic seizures (pseudoseizures) are functional events with a clinical presentation mimicking neurogenic seizures. There is no corresponding alteration in electroencephalographic activity. These events are often conversion reactions and are not under the patient’s conscious control. Up to 30% of patients referred to specialized epilepsy clinics for evaluations are ultimately diagnosed with psychogenic seizures, often with a delay of many years before the correct diagnosis is made. Psychogenic seizures often last longer than neurogenic events, and there usually is a brief or no postictal period. Patients can often recall events during psychogenic seizures, which would be diagnostic because this is not possible in neurogenic generalized seizures. Psychogenic seizures are classically manifested by forward-thrusting pelvic movements and head turning from side to side. Avoidance of noxious stimuli or gaze deviation away from the examiner are also suggestive that an event is psychogenic in origin. On laboratory testing, psychogenic seizure patients do not have a metabolic acidosis, which is nearly universal in those with generalized convulsive seizures.

**Pivotal Findings**

History and physical findings can be useful in differentiating seizure from other acute medical conditions. Retrograde amnesia, lateral tongue biting, and urinary incontinence are all suggestive of a neurogenic event however they are not specific and have been also reported in psychogenic seizures. Patients may experience an aura, which in essence is a focal seizure that then often generalizes. Auras are clinically defined by the area of the brain involved. Examples include alterations in sensation, autonomic deregulation such as sweating and flushing, aphasia, a sense of déjà vu, and
Symptoms

History taking in the patient with seizure is directed by two main questions. First, “Was the incident truly a seizure?” This is important because of the broad differential diagnosis for seizures (see Box 15.2) and the frequency of inaccurate descriptions of seizure-like activity from laypersons. In general, ictal events have five properties:
1. Abrupt onset: History should focus on any evidence of an aura.
2. Brief duration. Seizures rarely last longer than 90 to 120 seconds, although bystanders may overestimate the duration. Status epilepticus is the important exception.
3. Alteration of consciousness. Generalized seizures are manifest by loss of consciousness; focal seizures are often accompanied by an alteration in consciousness.
4. Purposeless activity. Automatisms and undirected tonic-clonic movements are common in ictal events. Tonic-clonic movements are rhythmic and generally do not involve head shaking.
5. Postictal state. This is an acute confusion state that typically occurs with all seizure types except focal and absence. This interval represents the transition from the ictal state back to the patient’s baseline mental status. It can last from minutes to hours, depending on which specific region of the brain triggered the seizure, seizure duration, age, and use of an antiepileptic drug (AED).

The second question to direct the history is, “Does this patient have a history of seizures?” If there is a documented history of seizures, ED evaluation may be limited to identifying precipitants and obtaining an AED level, when available. The history should focus on clinical factors known to decrease the seizure threshold, such as recent illness or trauma, drug or alcohol use, sleep deprivation, potential adverse drug-drug interactions with AEDs, medication noncompliance, recent change in anticonvulsant dosing regimens, or change in ictal pattern or characteristics.

Signs

The physiologic alterations associated with convulsive ictal activity include hypertension, tachycardia, and tachypnea from sympathetic stimulation. These signs typically resolve quickly after the seizure activity ceases. With more prolonged convulsions, skeletal muscle damage, lactic acidosis and, rarely, rhabdomyolysis may ensue. Autonomic discharges and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting (with aspiration risk), tongue biting, and airway compromise. All these signs are helpful discriminators in the differential evaluation of seizure-like spells, although the presence or absence of these findings neither confirms nor excludes seizure occurrence. Evidence of physical injury should be sought.

After the seizure activity has ceased, resting vital signs are evaluated. Fever and underlying infection can cause seizures, although there may be a low-grade temperature elevation immediately after a convulsive generalized seizure. Tachypnea, tachycardia, or an abnormal blood pressure that persists beyond the immediate postictal period may indicate toxic exposure, hypoxia, or a central nervous system lesion. Pertinent physical findings may include nuchal rigidity, stigmata of substance abuse, lymphenopathy suggestive of human immunodeficiency virus (HIV) disease or malignancy, dysmorphic features, or skin lesions. The examination should also focus on potential adverse sequelae of convulsive seizures, such as head trauma, oral and tongue injury, posterior shoulder dislocation, or back pain.

Finally, a complete neurologic examination is performed. A persistent focal deficit after a seizure (eg, Todd’s paralysis) often indicates the focal origin of the event but also can be evidence of an underlying stroke. Hyperreflexia and a positive Babinski reflex that resolve are indications that a seizure occurred. The patient should be carefully examined for signs of ongoing subtle convulsive or nonconvulsive status epilepticus, especially when there is a prolonged postictal depression of consciousness.

Ancillary Testing

Laboratory Testing

The serum glucose level should be determined in every seizing or postictal patient; women of reproductive age should be tested for pregnancy. If the diagnosis of seizure is uncertain, lactic acidosis may be detectable for up to 1 hour after the seizure resolves. Blood drawn in the field should be sent to the laboratory, along with blood drawn on arrival in the ED, if possible. Presence of a lactic acidosis in the field sample that resolves on ED testing supports a seizure diagnosis. Patients with a significant change in seizure pattern (eg, a substantial increase in seizure frequency despite medication compliance), or with an abnormal neurologic examination should undergo a more thorough laboratory assessment. The serum sodium level is the most important electrolyte to assess. Drug levels are appropriate in patients known or thought to be taking AEDs. Febrile patients should be evaluated for the source of the fever, including consideration of lumbar puncture.

For medically ill adults (eg, those with diabetes, cancer, or liver disease or those taking medications that can affect serum electrolytes) and in patients with a first-time seizure or substantial change in seizure pattern, serum electrolyte levels, including calcium and magnesium, are indicated. Liver function tests may be helpful if the history or physical examination suggests hepatic disease. Directed toxicology screens should be performed if substance abuse (particularly cocaine, amphetamines, and other sympathomimetic agents) or supratherapeutic use of aspirin or acetaminophen is suspected. Many drug of abuse screening tests do not detect agents such as synthetic cannabinoids, which can cause seizures. Headache may be a feature of the patient’s postictal state but, otherwise, the presence of fever and headache or sudden onset of headache is an indication for computed tomography (CT), lumbar puncture, or both.

Imaging Studies

An emergent cranial CT scan is indicated when a serious structural lesion is suspected on clinical grounds, including presence of a new focal deficit, persistent altered mental status, fever, recent trauma, persistent headache, history of cancer, anticoagulant use, suspicion or known history of acquired immunodeficiency syndrome (AIDS), age older than 40 years, and partial complex seizure. If magnetic resonance imaging (MRI) is readily available, it can be used instead of CT in most patients; MRI is more sensitive than CT and yields useful additional diagnostic and prognostic information. It is unlikely, however, that CT will miss a substantial CNS lesion. MRI is likely most useful in patients with a normal CT but recurrent seizure or focal electroencephalographic abnormalities.

In the fully recovered patient without headache and with normal mental status and neurologic examination findings who has had a single brief seizure, a cranial CT scan can be performed in the ED or at a follow-up visit at the discretion of the treating physician.

The literature on head CT imaging for first-time, nonfebrile seizures in children has been inconclusive. Emergent neuroimaging is indicated for children with medical or surgical comorbidities or in cases of focal seizures in children younger than 3 years, discussed in Chapter 174.
Electroencephalography

Obtaining an EEG is often logistically challenging in the ED, but can be invaluable for patients in whom the diagnosis is unclear or who remain altered. EEG is useful to diagnose nonconvulsive status epilepticus, monitor seizure activity after intubation and neuromuscular blockade, and help differentiate seizures from other nonneurologic presentations.

**DIAGNOSTIC ALGORITHM**

In patients suspected of having had a seizure, the first step is to determine whether the history from the patient or bystander(s) supports the diagnosis. Critical causes of seizures with specialized treatments include eclampsia, toxic ingestion (eg, isoniazid, tricyclic antidepressants), hypoglycemia, hyponatremia, and increased intracranial pressure. Box 15.3 presents the critical and emergent diagnoses that must be considered; Fig. 15.1 presents a diagnostic algorithm.

If the patient has a history of seizures, directed questions should be made to characterize the type of seizure. Information regarding the onset, presence of aura, type of seizure, and duration of ictal and postictal periods is key to determining whether the seizure is similar to previous seizures. If the seizure appears typical for the patient, the emergency clinician should identify if the patient is on an AED and inquire about potential triggers that can lower the seizure threshold, such as sleep deprivation, infections, and medications. If the patient is taking an AED for which a serum level can be measured (eg, phenytoin, carbamazepine, valproic acid) and found to be subtherapeutic, then additional medication can be given via the intravenous (IV) or oral (PO) route. The patient can then be discharged, with continued outpatient evaluation with the neurologist or primary care physician.

If the patient does not have a history of prior seizures, the diagnostic approach is directed to assess for potential precipitants, such as toxic ingestions, history of immunosuppression, pregnancy, or head trauma. Fingerstick blood glucose, pregnancy test in women, and serum sodium level are the most helpful laboratory tests. An ECG can identify characteristic changes from some toxic ingestions and evidence of risk for dysrhythmias (eg, accessory pathways, prolonged QTc). An obviously gravid patient may increase suspicion for eclampsia, but the condition can occur up to 8 weeks postpartum. A head CT scan can identify traumatic and atraumatic lesions or signs of increased intracranial pressure.

**BOX 15.3**

Critical and Emergent Diagnoses to Consider in a Patient With Seizure

**CRITICAL DIAGNOSES**

- Status epilepticus, regardless of cause
- Nonconvulsive status epilepticus
- Seizures with specialized treatments
  - Eclampsia
  - Toxic ingestion (eg, isoniazid [INH], tricyclic antidepressants)
  - Hypoglycemia
  - Hyponatremia
  - Increased intracranial pressure

**EMERGENT DIAGNOSES**

- Infection
- Posttraumatic seizures
- Serious mimics of seizure activity (eg, cardiogenic syncope)

Patients who arrive at the ED with ongoing seizure activity or who experience recurrent seizures without recovering from the postictal period are in status epilepticus. These patients generally require a full metabolic evaluation, complete blood count, and head CT. Up to 15% of patients who are successfully treated for convulsive status epilepticus remain in nonconvulsive status epilepticus; therefore, there should be a low threshold for obtaining a bedside EEG, especially if the postictal period is prolonged or automatisms are noted.

**EMPIRICAL MANAGEMENT**

**Prehospital Management**

Theprehospital management of the patient with seizures focuses on prompt recognition and treatment of hypoxia, hypotension, and hypoglycemia. Simultaneously, the patient should be protected from injury and, if possible, placed in a lateral decubitus position to reduce aspiration risk. Large retrospective reviews and expert consensus do not support the routine use of cervical spine immobilization unless there is high suspicion for head and neck trauma. A nasopharyngeal airway device may optimize oxygenation.

Because most seizures are of brief duration and self-limited, little intervention is generally required. Patients who are still seizing by the time of emergency medical services (EMS) arrival should be suspected to be in status epilepticus and priority should be on rapid administration of a benzodiazepine. Well-designed trials have shown the efficacy and safety of early administration of benzodiazepines during prehospital care. Intramuscular (IM) midazolam can be quickly administered; there is evidence that it is superior to IV lorazepam in adults and noninferior in children. Based on ease of administration and comparable outcome to IV lorazepam, we recommend IM midazolam as the first-line intervention is the field management of status epilepticus (Table 15.1 for dosing). We do not recommend the use of rectal diazepam in managing status because absorption is erratic and not as dependable as other routes.

**Emergency Department Management**

Patients who are actively seizing in the ED should be placed in a monitored bed. Management simultaneously focuses on identifying reversible causes, such as hypoxia and hypoglycemia, and initiating pharmacologic treatment. See Table 15.1 and Fig. 15.2.

For the seizing patient, ensuring central nervous system (CNS) perfusion and oxygenation is the priority. Oropharyngeal airways are contraindicated because they may induce gagging and vomiting and may damage the teeth or tongue. Oxygen may be administered to supplement immediate oxygenation and in preparation for possible rapid sequence intubation. Suction should be available but used carefully.

Lorazepam is the first-line treatment unless there is no vascular access, in which case we recommend midazolam IM. If the patient continues to seize despite initial therapy with lorazepam, second-line medications should be given. These include phenytoin, 20 mg/kg IV (at a maximum rate of 50 mg/min to avoid hypotension and arrhythmias), fosphenytoin (a water-soluble prodrug of phenytoin) at 20 phenytoin equivalents (PE)/kg IM or IV (maximum rate of 150 mg/min), and valproic acid, 20 to 40 mg/kg IV, administered at a rate of 3 to 6 mg/kg/min. If seizures continue, an additional half-loading dose of phenytoin, fosphenytoin, or valproic acid can be given. Although limited evidence exists, IV levetiracetam, bolus 1000 to 3000 mg over 15 minutes in adults, and 20 to 60 mg/kg, at a rate of 2 to 5 mg/kg/min 20 to 60 mg/min over 15 minutes in children, has been recommended.
If seizure activity continues, a careful reassessment should be done to identify reversible underlying processes, such as bleeding, drug overdose, and metabolic abnormalities that could have been missed until this point. Preparations for endotracheal intubation and administration of third-line therapies are indicated. Concomitantly, specific seizure syndromes should be considered in patients at risk. For example, isoniazid overdose can cause prolonged seizures refractory to benzodiazepines and requires pyridoxine to terminate the seizures. In seizing female patients of childbearing age, eclampsia may be the cause, and IV magnesium is the treatment of choice. Eclamptic seizures refractory to magnesium may respond to benzodiazepines or barbiturates, with or without phenytoin. Children and psychiatric patients at risk for water intoxication may be hyponatremic and require hypertonic saline therapy.

Third-line therapies for status epilepticus include pentobarbital, 5 mg/kg IV at a rate of 1 to 5 mg/kg/hr and then a 0.5 to 3.0-mg/kg/hr infusion as needed, phenobarbital, 20 mg/kg IV at 50 to 75 mg/min, midazolam, 0.2 mg/kg and then 0.1 to 0.4 mg/kg/hr, or propofol, 2 mg/kg IV at 2 to 5 mg/kg/hr and then a 5- to 10-mg/kg/hr infusion, as needed. Patients in status epilepticus should be admitted to the intensive care unit and have continuous electroencephalographic monitoring, which will be key to titrating the dosing of sedation for seizure termination.

Fig. 15.1. Diagnostic algorithm for the patient with seizure in the emergency department. AED, Antiepileptic drug; CT, computed tomography.
CHAPTER 15  Seizures

Seizures require more than one dose of a benzodiazepine in the ED, and are thought to have sufficient resources to comply reliably with follow-up instructions. When the diagnosis is uncertain and close follow-up is unlikely, longer observation or admission for observation should be considered.

Patients discharged home from the ED should receive state-specific guidance regarding driver’s license privileges, warning about potentially dangerous activities (eg, swimming, climbing ladders and heights, operating machinery), and information for prompt follow-up with a neurologist.

### Disposition

The appropriate disposition of a patient presenting to the ED with a seizure or history of a recent seizure must be individualized according to the underlying illness, likelihood of recurrence, indications for maintenance pharmacologic therapy, and state reporting regulations.

Patients may be discharged home with early referral to a neurologist if they have a normal neurologic examination findings, no significant medical comorbidities, and no known structural brain disease, do not require the use of an AED, did not require more than one dose of a benzodiazepine in the ED, and are thought to have sufficient resources to comply reliably with follow-up instructions. When the diagnosis is uncertain and close follow-up is unlikely, longer observation or admission for observation should be considered.

Patients discharged home from the ED should receive state-specific guidance regarding driver’s license privileges, warning about potentially dangerous activities (eg, swimming, climbing ladders and heights, operating machinery), and information for prompt follow-up with a neurologist.

</table>

EEG, Electroencephalogram; ET, endotracheal; IM, intramuscular; IV, intravenous; IN, intranasal; PR, per rectum.

**Prehospital care**

- Assess airway, breathing, and circulation
- Pulse oximetry
- Electrocardiogram
- Finger stick (give IV dextrose if glucose <60 mg/dL)
- Aspiration precautions (lateral decubitus)

**First-line therapy:**
- Diazepam 5 mg up to a max of 20 mg
- Lorazepam 2 mg up to a max of 10 mg
- Midazolam 10 mg IV/IM/intranasal

**Second-line therapy:**
- Phenytoin 20 mg/kg IV at a maximum rate of 50 mg/min (may give additional 5-10 mg/kg) or
- Fosphenytoin 20 PE/kg IM or IV at 150 mg/min (can give additional 5 PE/kg) or
- Valproic acid 20-40 mg/kg at 3-6 mg/kg/min or
- Levetiracetam 1000-3000 mg over 15 min

**Third-line therapy:**
- Intubation and electroencephalogram recommended
- Pentobarbital 5 mg/kg IV at 1-5 mg/kg/hr, then 0.5-3.0-mg/kg/hr infusion as needed or
- Phenobarbital 20 mg/kg IV at 50-75 mg/min or
- Midazolam 0.2 mg/kg IV, then 0.1-0.4 mg/kg/hr or
- Propofol 2 mg/kg IV at 2-5 mg/kg/hr, then 5-10 mg/kg/hr as needed

**Emergency department**

**Did the seizure stop?**

Yes

- Coordinate disposition plan with neurologist.
- Consider non convulsive status epilepticus in patients who have not returned to baseline.

No

**Did the seizure stop?**

Yes

No

**Fig. 15.2.** Management algorithm for status epilepticus.

**KEY CONCEPTS**

- The differentiation between seizures and other causes of altered mental or abnormal motor activity is not always straightforward and may require synthesizing the history, physical examination, laboratory results, and imaging data.
- Beginning in the out-of-hospital setting, patients with possible seizure activity should be protected from injury and assessed for hypoglycemia.
- Status epilepticus is defined as seizures lasting more than 5 minutes or repeat seizures while still postictal.
- Primary abortive therapy for seizures in the ED setting includes lorazepam; if diazepam is used in status epilepticus, it should be immediately followed by a loading dose of phenytoin, fosphenytoin, or valproic acid.
- Neuroimaging is recommended for patients with seizures who have head trauma, persistently abnormal mental status, focal neurologic abnormality, or HIV infection.
- Nonconvulsive status epilepticus should be considered in patients with a prolonged postictal state or otherwise unexplained coma.
- Patients with a first-time seizure who have no known structural brain pathology, normal serum glucose and sodium levels, and normal neurologic examination can be discharged from the ED with appropriate outpatient follow-up.

CHAPTER 15: QUESTIONS & ANSWERS

15.1. Which of the following is a generalized seizure disorder characterized by lack of a postictal state?
A. Atonic seizure disorder
B. Clonic seizure disorder
C. Myoclonic seizure disorder
D. Temporal lobe epilepsy
E. Tonic-clonic seizure disorder

Answer: A. Atonic seizure disorder, also known as atonic drop attack ictus, is notable among the generalized seizure disorders because of its lack of postictal state. Postictal states may be seen following tonic-clonic, clonic, and myoclonic seizures. Temporal lobe epilepsy is a focal, instead of generalized, seizure disorder.

15.2. What is the most common metabolic cause of seizure activity?
A. Hypercalcemia
B. Hyperglycemia
C. Hypermagnesemia
D. Hypocalcemia
E. Hypoglycemia

Answer: E. Seizure activity secondary to metabolic derangements is most commonly caused by hypoglycemia. The only treatment required in this situation may be intravenous (IV) glucose. Prolonged seizure activity may also cause hypoglycemia so that the cause and effect relationship may sometimes be reversed, and further therapy may be required.

15.3. A 15-year-old girl is brought to the emergency department for evaluation of a recent seizure. While awaiting laboratory results, she begins to have further seizure activity. Which of the following is the optimal first-line agent to terminate her seizure activity?
A. Fosphenytoin
B. Lorazepam
C. Phenobarbital
D. Phenytoin
E. Valproic acid

Answer: B. Benzodiazepines are the optimal first-line agents for stopping seizure activity in patients of all ages. Available agents include lorazepam, diazepam, and midazolam. Phenytoin is recommended as second-line therapy for adults with persistent seizure activity. The prodrug, fosphenytoin, can be administered more quickly, can be given intramuscularly, and has less of a tendency to cause hypotension. Second-line therapy for children is phenobarbital. Third-line therapy is pentobarbital, propofol, or a benzodiazepine infusion. Valproic acid should be considered for patients who are on chronic valproic therapy and whose levels are subtherapeutic.

15.4. A 24-year-old man is brought to the emergency department by emergency medical services (EMS). The patient’s mother reports that she found her son seizing on the floor of her living room approximately 30 minutes before arrival at the hospital. Two months ago, the patient returned from Mexico, where he had been incarcerated for 6 months. The mother reports that during the past 2 months she has seen her son consistently take his seizure medicine and several other pills for a “bad lung infection” he got in Mexico. She cannot remember the names of any of the medications. Several doses of IV lorazepam have been administered, with no effect on the patient’s seizure activity. Which of the following medications would be the most effective in aborting his seizure activity?
A. Diazepam
B. Magnesium sulfate
C. Phenytoin
D. Pyridoxine
E. Valproic acid

Answer: D. Several historical clues in this scenario point to tuberculosis being the “bad lung infection” in this patient. In patients with seizures that are refractory to benzodiazepines, isoniazid (a common medication for tuberculosis) overdose is a possibility and should be considered. Pyridoxine is the only fully effective pharmacologic treatment for toxic isoniazid seizures, although benzodiazepines have been shown to suppress seizure activity in some cases.

15.5. A mother arrives with her 10-year-old daughter (41 kg) who has been seizing for at least 10 minutes. The patient has a history of epilepsy, and a home dose of rectal diazepam has been ineffective. The mother states that the child has been in her usual state of good health until the seizure began, and there has been no history of trauma. Which of the following is the most appropriate initial action?
A. Administer 10 mg midazolam intramuscularly.
B. Consult neurology to obtain a bedside electroencephalogram.
C. Endotracheal intubation with vecuronium and etomidate.

Answer: B. Consult neurology to obtain a bedside electroencephalogram.
D. Establish vascular access and administer 2 mg of lorazepam.
E. Obtain an immediate computed tomography scan of the head.

**Answer:** A. Early, aggressive benzodiazepine administration is associated with decreased morbidity and mortality in status epilepticus. Intramuscular midazolam is superior to intravenous lorazepam; in addition, the dose of lorazepam is inadequate. Endotracheal intubation may ultimately be required, but is a secondary priority; use of a long-acting neuromuscular blockade agent, such as vecuronium, should be avoided. Cranial computed tomography may or may not be needed in this patient, depending on the response to benzodiazepine therapy. Bedside electroencephalograms are most useful in diagnosing nonconvulsive status epilepticus.

15.6. Paramedics present with a 24-year-old woman with a history of epilepsy after a seizure. She is somnolent but easily arousable and oriented to self and year. Her vital signs are normal, there are no signs of trauma, and an empty expired bottle of phenytoin is found in her purse. Her prehospital finger stick blood glucose level is 163 mg/dL. Which of the following treatment options is most correct?
A. Administer 20 mg/kg fosphenytoin intramuscularly and observe the patient until she returns to baseline.
B. Establish vascular access, and administer 4 mg lorazepam IV.
C. Establish vascular access, obtain a phenytoin level, and administer 1 to 2 mg lorazepam IV if the patient begins to seize.
D. Place the patient in a monitored setting, establish vascular access, and withhold diagnostic tests and treatments unless patient’s condition changes.

**Answer:** C. Medication noncompliance is a frequent cause of seizures in adults with epilepsy. It is recommended to check phenytoin levels before administering additional drug. Because the patient is not in status epilepticus, a low dose of benzodiazepines can be considered for patients who begin to seize while undergoing a period of observation.

15.7. Which of the following is not part of the routine emergency department evaluation and treatment of a 21-year-old healthy woman with a first seizure?
A. Discharge, with early outpatient neurology follow-up
B. Evaluation of serum electrolyte levels
C. Initiation of antiepileptic drug therapy.
D. Performance of cranial computed tomography

**Answer:** C. Adults presenting with a first seizure should undergo cranial computed tomography and evaluation of serum electrolyte and glucose levels because abnormalities would likely influence disposition while identifying potentially life-threatening conditions. For otherwise healthy adults with normal findings after evaluation, early outpatient follow-up can be considered. In some cases, initiation of antiepileptic drugs can be considered after a first seizure; however, this should be done in consultation with the neurologist responsible for outpatient follow-up.

15.8. Which of the following findings is uniformly reliable when trying to differentiate a seizure from a syncopal episode?
A. Loss of bowel or bladder continence
B. None of these
C. Report of nonpurposeful rhythmic movements from bystanders
D. Tongue biting
E. Transient confusion after the event

**Answer:** B. Unfortunately, although all the findings listed are seen more commonly with seizures than with syncope, all can occur in patients with syncope. Atonic seizures, commonly called drop attacks, are not followed by a postictal state.
Dizziness is an extremely common yet complex neurologic symptom that reflects a disturbance of normal balance perception and spatial orientation. Patients use the term dizziness to describe a variety of experiences, including sensations of motion, weakness, lightheadedness, unsteadiness, emotional upset, and depression. Dizziness is categorized into vertigo, near syncope, weakness, lightheadedness, unsteadiness, emotional upset, and describe a variety of experiences, including sensations of motion, stimulated by motion can be altered in one ear. This alteration can be readily diagnosed via history and specific diagnostic tests, a precise diagnosis is not always possible even after imaging and neurology consultation. Although one study showed that fewer than one in 500 patients discharged with a diagnosis of dizziness or vertigo experienced an important major vascular event in the month after discharge, another study found that patients discharged from the emergency department (ED) with a diagnosis of dizziness or vertigo had a twofold higher risk of a vascular event, such as stroke, on 3-year follow-up. Thus, the challenge for the emergency clinician is to identify the patient with a dangerous underlying disorder from the many others who have benign causes.

Pathophysiology

The maintenance of equilibrium and awareness of the body in relationship to its surroundings depend on the interaction of the visual, proprioceptive, and vestibular systems. Input from these three systems is connected to the cerebellum by way of the vestibular nuclei in the brainstem. Any disease that causes a mismatch of information from any two of these systems may give rise to symptoms of vertigo.

The vestibular apparatus helps maintain head position and stabilize head movement. It is housed in the inner ear, or labyrinth, which lies embedded in the petrous portion of the temporal bone. The vestibular apparatus consists of three semicircular canals and two otolithic structures (the utricle and the saccule). The semicircular canals and the utricle are connected to each other and contain endolymph. The semicircular canals provide information about movement and angular momentum, whereas the utricle (via otooliths, which are calcium carbonate particles attached to hair cells) provides information about head tilt and linear acceleration.

The semicircular canals are paired (left and right ears) structures that normally respond to motion in a symmetrical manner. With inner ear disease, the resting discharge or the discharge stimulated by motion can be altered in one ear. This alteration produces asymmetrical responses and results in the perception of vertigo. For example, freely moving otoliths that are inappropriately located within the semicircular canals, as in BPPV, can produce positional vertigo as the otoliths move under the influence of gravity and inappropriately signal that the head is turning when it is not.

Impulses leave the vestibular apparatus by the vestibular part of the acoustic nerve (cranial nerve [CN] VIII), enter the brainstem just below thepons and anterior to the cerebellum, and proceed to the four vestibular nuclei of the brainstem and to the cerebellum. From there, impulses travel along two pathways that contribute to the central manifestations of vertigo: (1) the medial longitudinal fasciculus (MLF) and (2) the vestibulospinal tract, which connect to the motor neurons that supply the muscles of the extremities. In individuals with healthy vestibular systems, these connections allow the eyes to compensate for body movement in different directions and to maintain a visual axis that is stable with respect to the environment. However, patients with a defective vestibular apparatus may experience false steps or other body movements, which is different from true ataxia, as they attempt to correct for an imagined change in position. Connections between the vestibular nuclei and the autonomic system account for the perspiration, nausea, and vomiting that commonly accompany an attack of vertigo. Connections between the vestibular nuclei and the cerebellum account for the modulating influence of this organ on motor activity.

Nystagmus occurs when the synchronized vestibular information becomes unbalanced. Typically, it results from unilateral vestibular disease, which causes asymmetrical stimulation of the medial and lateral rectus muscles of the eye. This unopposed activity causes a slow movement of the eyes toward the side of the stimulus, regardless of the direction of deviation of the eyes. Then the cerebral cortex corrects for these eye movements and rapidly brings the eyes back to the midline, only to have the process repeated. By convention, the direction of nystagmus is denoted by the direction of the fast “cortical” component.

Near-syncope is due to the global reduction of blood flow to the brain. Because people rise from the supine and sitting positions frequently throughout the day, a complicated neural reflex has evolved such that the central nervous system (CNS) puts out a stimulus causing vasoconstriction and hence preservation of blood flow to the brain upon standing. When the reflex fails or is interfered with (eg, orthostatic hypotension, vasovagal syndrome, and environmental factors), pallor, nausea, rubbery legs, diaphoresis, and constriction of the visual field occur.

Disequilibrium occurs due to a disruption between the sensory inputs and motor outputs, and this often results in an unsteady gait. Disequilibrium is usually a disease of older adults because there is an age-related decline in the ability of the CNS to process sensory inputs, as well as a decline in control of postural reflexes. Disequilibrium is often exacerbated by unfamiliar surroundings, uneven ground, or poor lighting. Cervical spondylosis is a common cause and leads to spinal cord myelopathy. Patients have poor proprioception in the legs leading to a stiff-legged gait.

BOX 16.1
Causes of Vertigo

PERIPHERAL CAUSES
- Benign paroxysmal positional vertigo (BPPV)
- Vestibular neuritis (or neuronitis)/labyrinthitis
- Ménière’s disease
- Foreign body in ear canal
- Acute otitis media
- Perilymphatic fistula
- Trauma (labyrinth concussion)
- Motion sickness
- Acoustic neuroma

CENTRAL CAUSES
- Vertebral basilar artery insufficiency
- Cerebellar hemorrhage or infarction
- Tumor
- Migrainous vertigo
- Multiple sclerosis
- Post-traumatic injury (temporal bone fracture, postconcussive syndrome)
- Infection (encephalitis, meningitis, brain abscess)
- Temporal lobe epilepsy
- Subclavian steal syndrome

The mechanism of nonspecific dizziness is poorly understood but is thought to result from impaired central integration of sensory signals. Patients sometimes have difficulty describing their dizziness and are often in a hypervigilant state. Their exaggeration of reactions to normal changes may induce psychological stress. Table 16.1 lists the pathophysiology for selected causes of peripheral vertigo.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis for peripheral and central vertigo is summarized in Box 16.1. More detailed information is given on selected causes in Table 16.2. A symptom-based approach to categorizing dizziness identifies four categories: (1) vertigo, (2) near syncope, (3) disequilibrium, and (4) nonspecific dizziness. Unfortunately, this approach is imprecise and new categorization systems have been proposed. One system uses three general categories: (1) acute severe dizziness (eg, vestibular neuritis, stroke), (2) recurrent attacks of dizziness (eg, Ménière’s disease, transient ischemic attack (TIA), and (3) recurrent positional dizziness (eg, BPPV, cerebellar tumor, multiple sclerosis). Another system uses a “timing and triggers” approach, resulting in four categories: (1) acute vestibular syndrome (eg, vestibular neuritis, cerebellar stroke), (2) spontaneous episodic vestibular syndrome (eg, Ménière’s disease, vertebrobasilar insufficiency [VBI]), (3) triggered episodic vestibular syndrome (eg, BPPV), and (4) chronic vestibular syndrome (eg, polysensory dizziness, psychiatric syndromes, posterior fossa lesions). Neither of these approaches has been prospectively validated or systematically studied as a diagnostic paradigm, but they provide an alternative way of thinking about dizziness and vertigo.

If the patient has true vertigo, then the cause is either a peripheral lesion, such as from the vestibular system, or a central process, such as cerebrovascular disease or a neoplasm. This distinction is important because peripheral disorders are generally benign, whereas central disorders usually have serious consequences. Box 16.1 lists causes of peripheral and central vertigo. Table 16.3 summarizes the different characteristics of peripheral and central vertigo.

Pivotal Findings

Symptoms

Vertigo is described as the environment spinning; however, any sensation of disorientation in space or sensation of motion can qualify as vertigo. Vertigo is generally associated with some degree of nausea, vomiting, pallor, and perspiration. Peripheral vertigo is not associated with a change in mentation or syncope. A sensation of imbalance often accompanies vertigo, and this can be difficult to distinguish from true instability, disequilibrium, or ataxia, findings of which indicate a higher likelihood of a central process.

The time of onset and the duration of vertigo are important clues to the cause. For example, episodic vertigo produced primarily by a change in position and lasting less than a minute suggests BPPV. A patient with BPPV often thinks his vertigo is constant, because every time he moves his head, he gets vertigo. By teasing out how long each individual episode of vertigo lasts, the physician will be led to the correct diagnosis of BPPV. Acute vestibular syndrome has an arbitrary cutoff of continuous vertigo for at least 1 day, in part to help differentiate acute vestibular syndrome from attacks of Ménière’s disease or prolonged migrainous vertigo.

The presence of auditory symptoms suggests a peripheral cause of the vertigo, usually on the side of end-organ disturbance. Acoustic neuroma, which can rarely cause vertigo, is usually associated with progressive unilateral hearing loss, typically of several months’ duration. Hearing loss, vertigo, and tinnitus form the characteristic triad of Ménière’s disease. Labyrinthitis is differentiated from vestibular neuritis in that the former is associated with hearing loss.

Head injury can cause vertigo occasionally from intracerebral injury and more commonly from labyrinth concussion. Neck injury can cause vertigo from vertebral artery dissection, resulting in posterior circulation ischemia.

Associated neurologic symptoms such as imbalance, dysarthria, or numbness raise the likelihood of TIA and stroke. Although the vast majority of patients with isolated dizziness/vertigo do not have TIA or stroke, they can be the only initial symptoms of cerebellar and other posterior circulation bleeds, TIAs, and infarction. In these cases, diagnostic testing is directed by assessment of risk based on the history and physical examination. Older age, male sex, hypertension, coronary heart disease, diabetes, and atrial fibrillation put patients at higher risk for TIA and stroke. Many medications (such as, aminoglycosides, anti-convulsants, alcohol, quinine, quinidine, and minocycline) have direct vestibulotoxicity.

<tr>
<td>1. Benign paroxysmal positional vertigo (BPPV)</td>
<td>Short-lived (typically less than 30 seconds), positional, fatigable episodes; more often in older adults.</td>
<td>Nausea, vomiting</td>
<td>Certain positions can precipitate vertigo. Positive result on Hallpike test (posterior semicircular canal) or supine roll test (horizontal canal).</td>
</tr>
<tr>
<td>2. Vestibular neuritis/labyrinthitis</td>
<td>Vertigo may develop suddenly or evolve over several hours, usually increasing in intensity for hours, then gradually subsiding over several days but can last weeks. Can be worsened with positional change. Sometimes history of viral infection precedes initial attack. Highest incidence is found in third and fifth decades.</td>
<td>Nausea, vomiting</td>
<td>Spontaneous nystagmus beating away from the side of the lesion may be present in the first few hours. Positive head impulse test. Hearing is normal in vestibular neuritis; hearing loss for labyrinthitis.</td>
</tr>
<tr>
<td>3. Ménière’s disease</td>
<td>Recurrent episodes of severe rotational vertigo usually lasting hours. Onset usually abrupt. Attacks may occur in clusters. Long symptom-free remissions.</td>
<td>Nausea, vomiting, tinnitus, hearing loss (hearing loss required for diagnosis)</td>
<td>Positional nystagmus is not present; hearing loss</td>
</tr>
<tr>
<td><strong>CENTRAL</strong></td>
<td></td>
<td></td>
<td></td>

<tr>
<td>1. Vascular disorders</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>A. Vertebrobasilar insufficiency (VBI)</td>
<td>Should be considered in any patient of advanced age with isolated new-onset vertigo without an obvious cause. More likely with history of atherosclerosis. Can occur with neck trauma. May be preceded by an episode usually lasting minutes.</td>
<td>Often headache; usually neurologic symptoms including dysarthria, ataxia, weakness, numbness, double vision; tinnitus and hearing loss uncommon but possible</td>
<td>Neurologic deficits usually present, but initially neurologic examination can be normal.</td>
</tr>
<tr>
<td>B. Cerebellar hemorrhage</td>
<td>Sudden onset of severe symptoms.</td>
<td>Headache, vomiting, ataxia</td>
<td>Signs of toxicity. Dysmetria, true ataxia. Ipsilateral sixth cranial nerve palsy may be present.</td>
</tr>
<tr>
<td>C. Occlusion of posterior inferior cerebellar artery (Wallenberg’s syndrome)</td>
<td>Vertigo associated with significant neurologic complaints.</td>
<td>Nausea, vomiting, loss of pain and temperature sensation, ataxia, hoarseness</td>
<td>Loss of pain and temperature sensation on the side of the face ipsilateral to the lesion and on the opposite side of the body, paralysis of the palate, pharynx, and larynx. Horner’s syndrome (ipsilateral ptosis, miosis, and decreased facial sweating).</td>
</tr>
<tr>
<td>2. Head trauma</td>
<td>Symptoms begin with or shortly after head trauma. Positional symptoms most common type after trauma. Self-limited symptoms that can persist weeks to months.</td>
<td>Usually mild nausea</td>
<td>Occasionally, basilar skull fracture.</td>
</tr>
<tr>
<td>3. Migrainous vertigo</td>
<td>Vertigo attacks can occur during the headache (in one study of 33 patients 24% always had headache with vertigo and 67% had headache sometimes with vertigo) but often occur during the headache-free interval. Most patients have a family history of migraine. Syndrome usually begins in adolescence.</td>
<td>Imbalance, head motion intolerance, photophobia, phonophobia, oscillopsia</td>
<td>No residual neurologic or otologic signs are present after attack.</td>
</tr>
<tr>
<td>4. Multiple sclerosis</td>
<td>Vertigo presenting symptom in 7% to 10% and appears in the course of the disease in a third. Onset may be severe. Disease onset usually between ages of 20 and 40. Often history of other attacks with varying neurologic signs or symptoms.</td>
<td>Nausea and vomiting, which may be severe</td>
<td>May have horizontal, rotary, or vertical nystagmus. Nystagmus may persist after the vertiginous symptoms have subsided. Internuclear ophthalmoplegia (INO) highly suggestive for multiple sclerosis. INO is diagnosed when, on eye movement, the adducting eye shows little to no movement while the abducting eye moves normally.</td>

is suspected, which also can cause VBI, the pulse and blood pressure, as the cause of dizziness. When subclavian steal syndrome may be the key to identifying a cardiovascular etiology or drug associated with an upper respiratory tract infection or descent atherosclerosis and risk for TIA or stroke. The vertebral artery can likely when the pattern of nystagmus is purely vertical, downbeating nystagmus is directly related to the degree of acute vestibular changing with gaze, or spontaneous pure torsional. Severity of nystagmus is directly related to the degree of acute vestibular hypofunction that occurs. Spontaneous nystagmus usually occurs in severe cases. In mild cases, vestibular asymmetry is less prominent, so spontaneous nystagmus may be subtle or present only for the first few hours. After that it may be only detectable when the patient looks away from the damaged ear or if the examiner performs a head impulse test.

BPPV, Benign paroxysmal positional vertigo; TIA, transient ischemic attack.

**Physical Examination**

**Vital Signs.** The vital signs, including orthostatic changes, may be the key to identifying a cardiovascular etiology or drug effect as the cause of dizziness. When subclavian steal syndrome is suspected, which also can cause VBI, the pulse and blood pressure should be checked on both sides.

**Head and Neck.** Carotid or vertebral artery bruits suggest atherosclerosis and risk for TIA or stroke. The vertebral artery can be auscultated in the supraventricular region.

Fluid in the middle ear as a result of a middle ear infection may cause mild vertigo, as can occlusion of the eustachian tubes associated with an upper respiratory tract infection or descent barotrauma. A perforated or scarred eardrum may indicate a perilymphatic fistula, especially if the history includes previous trauma.

Examination of the eyes is critical in assessing a patient with vertigo. Pupillary abnormalities may indicate third cranial nerve or descending sympathetic tract involvement. Papilledema suggests increased intracranial pressure. Relatively subtle extracocular movement abnormalities can be the only clue to a cerebellar hematoma. A sixth cranial nerve palsy ipsilateral to the hemorrhage may result from early brainstem compression by the expanding hematoma. Internuclear ophthalmoplegia, which indicates brainstem pathology, is recognized when the eyes are in a normal position on straight-ahead gaze, but on eye movement the adducting eye (CN III) is weak or shows no movement while the abducting eye (CN VI) moves normally (although often displaying a coarse nystagmus). This finding indicates an interruption of the MLF on the side that demonstrates third cranial nerve weakness and is virtually pathognomonic of multiple sclerosis.

Abnormal nystagmus is the cardinal sign of inner ear disease and the principal objective evidence of abnormal vestibular function. Positional nystagmus, induced by changing the position of the head, strongly suggests an organic vestibular disorder, typically BPPV. Noting the characteristics of the nystagmus can help to differentiate benign peripheral causes from serious central causes (see Table 16.3). Central causes of nystagmus are more likely when the pattern of nystagmus is purely vertical, downbeating (fast phase beating toward the nose), non-fatigable, direction changing with gaze, or spontaneous pure torsional. Severity of nystagmus is directly related to the degree of acute vestibular hypofunction that occurs. Spontaneous nystagmus usually occurs in severe cases. In mild cases, vestibular asymmetry is less prominent, so spontaneous nystagmus may be subtle or present only for the first few hours. After that it may be only detectable when the patient looks away from the damaged ear or if the examiner performs a head impulse test.

**Neurologic Examination.** The presence of cranial nerve deficits suggests a space-occupying lesion in the brainstem or cerebellopontine angle, such as an acoustic neuroma, which can rarely manifest with vertigo.

Cerebellar function is tested several ways. Dysmetria is the inability to arrest a muscular movement at the desired point and should be assessed with finger-to-finger or finger-to-nose pointing. Dysdiadochokinesia (an inability to perform coordinated muscular movement smoothly) is assessed with rapid alternating movements.

Gait assesses ataxia, which when of recent and relatively sudden onset suggests cerebellar hemorrhage or infarction in the distribution of the posterior inferior cerebellar artery or the superior cerebellar artery. Ataxia that is slowly progressive suggests chronic cerebellar disorders. True ataxia may be difficult to discern from the unsteadiness that occurs when a patient with significant vertigo attempts to walk, although other findings (such as, nystagmus and dysmetria) can help narrow the differential diagnosis. This examination is performed when the patient is both sitting and standing, because truncal ataxia, which is seen in midline cerebellar lesions, may become obvious only when the patient has to sit, stand, or walk unaided. Any marked abnormality (eg, consistent falling or a grossly abnormal gait) should suggest a central lesion, especially in a patient whose vertiginous symptoms have subsided. Patients with an acute peripheral vestibular lesion typically can stand, although they will likely veer toward the side of the lesion. Patients with central vertigo often cannot stand without support. The main features of a cerebellar gait are a wide base, unsteadiness, irregularity of steps, tremor of the trunk, and lurching from side to side. The unsteadiness is most prominent on arising quickly from a sitting position, turning quickly, or stopping suddenly while walking. Patients with gait ataxia also cannot perform heel-to-toe walking.

**Positional Testing.** Positional testing can confirm the diagnosis of BPPV. The Hallpike test, also known as the Dix-Hallpike
test or the Nylen-Barany test, confirms the diagnosis of posterior canal BPPV, which is the most common variant of BPPV. This test should be reserved for those patients suspected of positional vertigo, and caution should be exercised in performing it in patients with acute vestibular syndrome (acute and constant dizziness, nausea or vomiting, unsteady gait, nystagmus, and intolerance to head motion lasting more than a day) whose main differential diagnosis include vestibular neuritis and stroke. Some evidence indicates that provocative testing may lead to a nonspecific worsening of symptoms in these patients, which could be misinterpreted as diagnostic of a peripheral disorder before stroke has been adequately excluded. Thus, if a patient is actively experiencing vertigo during history taking and there has been no immediate prior head movement, then the Hallpike test should not be performed because this history is inconsistent with BPPV, which requires head movement to elicit symptoms.

The Hallpike test is performed with the patient sitting up. The examiner turns the patient’s head 45 degrees to one side and then moves the patient from the upright seated position to a supine position with the head overhanging the edge of the gurney (Fig. 16.1). The patient is queried for the occurrence of vertigo, and the eyes are observed for nystagmus after a latency period on the order of a few seconds. In a patient with classic posterior canal BPPV, the nystagmus usually lasts 5 to 30 seconds and is combined upbeat (the fast phase beats toward the forehead) and ipsilateral torsional (the top pole beating toward the downward ear). The patient is then brought back up to the seated position, and the test is repeated with the head turned 45 degrees to the other side. Findings are summarized in Box 16.2.

In general, if the patient has posterior canal BPPV, only one side should be positive during the Hallpike test, although it is theoretically possible to have otoliths inappropriately located in both right and left posterior semicircular canals. Assuming unilateral involvement, the downward ear indicates the involved side, which is the side to start with when treating with the curative bedside Epley maneuver. If the patient pre-identifies the side that causes the symptoms, we test the opposite side first, and this should result in a negative Hallpike test. We then test the other side and, if positive, continue on to complete the Epley maneuver. (The first step of the Epley maneuver is the first part of the Hallpike test, which involves turning the head 45 degrees to the involved side and then laying the patient with the head hanging over the edge of the gurney.)

If the Hallpike test is negative or seems to be positive bilaterally, one can use the supine roll test to test for the horizontal canal variant of BPPV. The patient starts in the supine position and unlike the Hallpike test, the head does not need to overhang the edge of the gurney. The head is then turned 90 degrees to each side. With a positive test, the patient will have reproduction of symptoms and horizontal nystagmus with the head turned in either direction. The side that is involved is the one with the more intense symptoms and more dramatic nystagmus. Note that the nystagmus will change direction, but this is due to a change in head position and not from a change in gaze direction and so is not concerning for a central cause of vertigo. A video of a case involving failed attempts at the barbeque roll to treat horizontal BPPV, followed by conversion to posterior canal BPPV after a Gufoni maneuver (with resultant cure using the Epley maneuver), can be found at www.youtube.com/watch?v=dJOAOGmpM.

The head impulse, or head-thrust test, is used to diagnose vestibular neuritis and labyrinthitis. The physician stands face to face with the patient and places both hands on the sides of the patient’s head. The patient stares at the examiner’s nose while the examiner rapidly turns the patient’s head approximately 10 degrees to one side. Normally the patient’s eyes should keep focusing on the examiner’s nose. If there is a problem with the vestibular nerve, the eyes will temporarily move along with the head. A corrective saccade will then occur, in which the eyes jerk back toward the midline. If a saccade is seen, this denotes a positive head-thrust test result and indicates vestibular nerve dysfunction. In general, eliciting a positive head impulse test indicates a benign peripheral cause of vertigo, such as vestibular neuritis. The head must be turned rapidly because a false negative test may result otherwise, leading to incorrectly suspecting a central cause.

HINTS. HINTS (Head Impulse test, Nystagmus, Test of Skey) is a bedside oculomotor examination test that has been proposed as a way to differentiate central from peripheral vertigo in patients with acute vestibular syndrome. The majority of such patients will have vestibular neuritis, but the HINTS examination may help to identify the smaller numbers who are suffering from stroke or other central causes of vertigo.

The first part of HINTS is the head impulse test and as described earlier, a corrective saccade indicates a positive test and is more reassuring for vestibular neuritis. The second part (nystagmus) refers to a direction change of nystagmus on eccentric gaze. For example, when the patient looks to the left, the fast component beats to the left; and when the patient looks to the right, the fast component beats to the right. This direction-changing nystagmus may indicate a stroke in a patient with acute vestibular symptoms.
syndrome. The third part (test of skew) refers to vertical ocular misalignment during alternate cover testing and its presence is suggestive of brainstem strokes. Using HINTS requires experience and practice, and it should only be used in patients with a first ever episode of constant vertigo from acute vestibular syndrome as was required in the clinical studies involving the HINTS exam. For example, applying the head impulse test in a patient who is dizzy from BPPV would result in a negative test and may cause the emergency physician to incorrectly conclude that the patient’s dizziness could be from a central cause of vertigo. In general, performing both the Hallpike test and the HINTS examination on the same patient is not appropriate. Instead, BPPV and acute vestibular syndrome should be distinguished from each other by history and by the presence of spontaneous nystagmus.

Ancillary Testing

Most routine laboratory testing is not helpful in the evaluation of a vertiginous patient except for a finger-stick blood glucose test. Blood counts and blood chemistries are helpful if the dizziness is life-threatening. BPPV and vestibular neuritis are likely the most common peripheral causes of vertigo encountered in the ED.

Radiologic Imaging. Acute vertigo by itself does not warrant urgent computed tomography (CT) or magnetic resonance imaging (MRI) in all patients, particularly patients in whom a clear picture of peripheral vertigo emerges, such as with BPPV. Risk factor assessment can be helpful in deciding which patients warrant imaging: Older age, male sex, hypertension, coronary artery disease, diabetes, and atrial fibrillation put patients at higher risk for more serious causes of dizziness and vertigo. If cerebellar hemorrhage, cerebellar infarction, or other central lesions are suspected, emergent CT or MRI of the brain is indicated. MRI, when available, has become the diagnostic modality of choice for posterior fossa (cerebellum, medulla, andpons) lesions, as well as for rare causes of vertigo, including acoustic neuroma and multiple sclerosis.

BPPV, Benign paroxysmal positional vertigo.

EMPIRICAL MANAGEMENT

Management is based on an accurate diagnosis that distinguishes the serious central causes of vertigo from the less serious peripheral causes. Any suggestion of cerebellar hemorrhage warrants immediate imaging with CT or MRI and neurosurgery consultations. VBI should be considered in any patient of advanced age or at high risk of cerebrovascular disease who presents with isolated, new-onset vertigo without an obvious cause. Because of the possibility of progression of new-onset VBI in the first 24 to 72 hours, hospital or observation unit admission and consideration of early magnetic resonance angiography (MRA) are reasonable, even in a stable patient. Changing or rapidly progressive symptoms suggest impending posterior circulation occlusion. If CT or MRI excludes hemorrhage as the source of the patient’s symptoms, an immediate neurologic consultation, further imaging (such as, angiography), and possible anticoagulation are indicated.

Canalith repositioning maneuvers, such as the Epley maneuver, are extremely effective in treating BPPV, including in the ED setting. The Epley maneuver, which is used to treat posterior semicircular canal BPPV, involves four to five sequential rotations of the head, holding each position for approximately 30 seconds or until the nystagmus and vertigo resolves, as demonstrated in Figure 16.3. Failure of the Epley maneuver is usually due to one of two problems: First, the head is lifted too high during the third step of the Epley maneuver, in which the patient rolls onto his side and looks toward the ground. Second, the Epley maneuver is often inappropriately applied to a patient who has vestibular neuritis, which is distinct from BPPV (see Table 16.4).

The “barbecue roll” is a simple maneuver that can be used to treat the horizontal canal variant of BPPV, which is diagnosed by the supine roll test. The patient lies flat on the gurney with the head turned 90 degrees to the involved side. The head is then rotated in 45-degree intervals away from the involved side (each turn is held approximately 30 seconds or until nystagmus and vertigo resolve). Eventually the patient needs to turn over into the prone position. The maneuver is completed once the head has returned to the original starting position. The Gufoni maneuver is an alternative treatment for the horizontal canal variant (see http://careguides-videos.med.umich.edu/media/Gufoni+Left+Horizontal-Geotropic/1_3si1rw8/20345631).

Two relatively recent practice guidelines were published that included information on the use of medications to treat BPPV. One found no evidence to support a recommendation of any medication in the routine treatment of BPPV. The other
CHAPTER 16
Dizziness and Vertigo

... information it is receiving, and benzodiazepines can interfere with this process. Meclizine (Antivert) 25 mg every 4–6 hours can be given in the ED, although its time of onset is approximately 1 hour. Because it can exacerbate symptoms in patients with non-vertiginous types of dizziness, it should be reserved for patients with BPPV who have failed the Epley maneuver or for patients who have an alternative diagnosis of peripheral vertigo, such as vestibular neuritis. Transdermal scopolamine has shown disappointing results for treatment of peripheral vertigo but may be considered a third-line option.

Vestibular neuritis, which is inflammation of the eighth cranial nerve, is thought to have a similar mechanism to Bell palsy. Patients typically have severe vertigo for days with gradual resolution over weeks to months. Nystagmus may be spontaneous during the first several hours of symptoms, and patients will have a positive head impulse test. Although the evidence is weak, corticosteroids are possibly helpful using a 22-day taper of methylprednisolone beginning with a dose of 100 mg each morning.

Antivirals, such as valacyclovir, are not helpful in the treatment of vestibular neuritis. Until certainty is reached, we recommend steroid treatment with prednisone (or methylprednisolone) with a gradual taper over 2 to 3 weeks, although shared decision making with the patient is an acceptable alternative.

Some cases of Ménière’s disease have been treated successfully with vasodilation and diuretic therapy. Diets low in sodium and...
CAFFEINE AND CESSION OF SMOKING have also been helpful. However, the diagnosis of Mènière’s disease requires documentation of hearing loss, so this is not a diagnosis that can be typically made during an ED visit.

DISPOSITION

Documented or suspected VBI or cerebellar hemorrhage or infarction require diagnostic evaluation, treatment, and, usually, hospitalization. In patients older than age 55 with vascular risk factors, admission for observation and imaging of cerebral vasculature should be considered if the diagnosis is not certain. Most younger patients with peripheral causes of vertigo can be discharged from the ED after symptoms have been controlled. Some patients with peripheral vertigo may have such severe symptoms (eg, intractable vomiting, inability to walk) despite medications that they require hospital admission for intravenous hydration, vestibular suppressants, and antiemetics. Reassessment of neurologic examination findings and response to therapy are important to ensure that the vertigo is not of central origin. Discharged patients should receive primary care, neurology, or otolaryngology follow-up, particularly if symptoms are not significantly improved within 72 hours or are worsening despite symptomatic treatment.

KEY CONCEPTS

1. Associated neurologic complaints, such as imbalance, dysarthria, or numbness raise the likelihood of TIA or stroke as the cause of a patient’s dizziness/vertigo.
2. Benign paroxysmal positional vertigo (BPPV) requires head movement to elicit symptoms. Consequently, the Hallpike test should not be performed if the patient is actively symptomatic during history taking (and the patient’s head has not been recently moved) because such a history is inconsistent with BPPV.
3. When performing the Hallpike test, the head should be turned to the side 45 degrees prior to laying the patient back into the head-hanging position.
4. A positive Hallpike test should elicit upbeating nystagmus.
5. The Epley maneuver is used to treat posterior semicircular canal BPPV, which is the most common subtype of BPPV.
6. Central causes of nystagmus are more likely when the pattern of nystagmus is purely vertical, downbeating (fast phase beating toward the nose), non-fatigable, direction changing with gaze, or spontaneous pure torsional.
7. The presence of auditory symptoms suggests a peripheral cause of the vertigo.
8. Acute vestibular syndrome is diagnosed when dizziness develops acutely; is constant; is accompanied by nausea or vomiting, unsteady gait, nystagmus, and intolerance to head motion; and persists for longer than a day.
9. Neck injury can cause vertigo from vertebral artery dissection, resulting in posterior circulation ischemia.
10. Abnormal nystagmus is the cardinal sign of inner ear disease and the principal objective evidence of abnormal vestibular function.
11. HINTS (Head Impulse test, Nystagmus, Test of Skew) is a bedside ocular motor examination test that has been proposed as a way to differentiate central from peripheral vertigo in patients with a first ever onset of constant vertigo from acute vestibular syndrome.
12. Meclizine (Antivert) has a time of onset of approximately 1 hour.
13. Do not prescribe benzodiazepines to patients with vestibular neuritis or labyrinthitis who are discharged home. Such medications can interfere with the process of vestibular rehabilitation.

CHAPTER 16: QUESTIONS & ANSWERS

16.1. Which maneuver should be used to treat benign paroxysmal positional vertigo (BPPV) of the horizontal semicircular canal?
A. Barbeque roll
B. Epley maneuver
C. Hallpike test
D. Head impulse test

Answer: A. The Epley maneuver is used to treat posterior canal BPPV. The Hallpike test is used to diagnose posterior canal BPPV. The head impulse test is used to diagnose vestibular neuritis and labyrinthitis. The supine roll test, in which the patient lies flat on the gurney and the head is turned to each side, is used to diagnose horizontal canal BPPV, whereas the barbeque roll maneuver is used to treat the horizontal variant of BPPV.

16.2. Which of the following examination findings requires further testing and/or consultation with a specialist?
A. Direction changing nystagmus on change in head position
B. Direction changing nystagmus on change in lateral gaze
C. Positive head impulse test
D. Torsional upbeat nystagmus during Hallpike test

Answer: B. Direction changing nystagmus on change in gaze is concerning for a central cause of vertigo and makes up part of the HINTS test.

16.3. Internuclear ophthalmoplegia most often suggests a diagnosis of:
A. Horizontal canal BPPV
B. Labyrinthitis
C. Multiple sclerosis
D. Vestibular neuritis

Answer: C. Internuclear ophthalmoplegia is diagnosed when, on eye movement, the adducting eye shows little to no movement while the abducting eye moves normally. In a vertigo patient, this finding is virtually pathognomonic for multiple sclerosis.

16.4. Which of the following is a central cause of vertigo?
A. Labyrinthitis
B. Ménière’s disease
C. Vertebrobasilar insufficiency
D. Vestibular neuritis

Answer: C. All the other causes are peripheral.

16.5. Continuous vertigo of what duration is used to define acute vestibular syndrome?
A. 1 hour
B. 8 hours
C. 24 hours
D. 1 week

Answer: C. Acute vestibular syndrome has an arbitrary cutoff of continuous vertigo for at least 1 day in part of help differentiate acute vestibular syndrome from attacks of Ménière’s disease or prolonged migrainous vertigo.
Differential Diagnosis Considerations

The differential diagnosis of headache is complex due to the large number of potential disease entities and the diffuse nature of many types of pain in the head and neck region (Table 17.1). In evaluating the patient with a primary complaint of headache, the top priority is to exclude the causes with significant morbidity and mortality: SAH, ICH, meningitis, encephalitis, and mass lesions. Carbon monoxide is an exogenous toxin, the effects of which may be reversible by removing the patient from the source and administering oxygen. Carbon monoxide poisoning is a rare example of a headache in which relatively simple interventions may quickly improve a critical situation; however, returning the patient to the poisoned environment without a diagnosis could be lethal (see Chapter 153).

Pivotal Findings

Physical findings may be minimal or nonspecific, even in serious causes of headache, so the history is the pivotal part of the evaluation (Table 17.2).

1. Determine the pattern and the onset of the pain. Patients may remember having had frequent and recurrent headaches similar to the one they have on the current ED visit; a marked variation in the headache pattern can signal a new or serious problem. A rapid and severe onset of pain (“thunderclap”) has been associated with serious causes of headache, and this warrants strong consideration of a cerebrovascular etiology. Slow onset of headache should not be solely relied on to rule out a potentially life-threatening cause, and the nature of the onset usually is not possible to ascertain if the headache came on during sleep.

Almost all studies dealing with subarachnoid bleeding report that patients moved from the pain-free state to severe pain within seconds to minutes. The thunderclap headache is common in acute presentations of SAH but is not highly specific. If the patient with moderate or severe headache can indicate the precise activity in which he or she was engaging at the time of the onset of the headache, the suddenness of onset warrants consideration of SAH. Careful questioning about the onset of headache may lead to the correct diagnosis of SAH, even if the pain is improving at the time of evaluation.

2. The patient’s activity at the onset of the pain may be helpful. Headaches that come on during exertion have a relationship to vascular bleeding. Additionally, although the syndrome of postcoital headache is well known, coitus is also recognized as an activity associated with SAH, so a pattern of previous postcoital headache is key; as is understanding whether the current headache fits that pattern. Postcoital headaches require the same evaluation on initial presentation as any other exertion-related head pain.

3. If there is a history of head trauma, the differential diagnosis shifts markedly toward epidural and subdural hematomas, traumatic SAH or intraparenchymal hemorrhage, skull fracture and closed head injuries, such as concussion and diffuse axonal injury.

4. The intensity of head pain is difficult to quantify objectively. Almost all patients who come to the ED consider their headaches to be severe. Use of a pain scale with appropriate explanation may help differentiate patients initially but has more value in monitoring their response to therapy. Rapid resolution
Unilateral pain is more suggestive of migraine or localized inflammatory process in the skull (eg, sinus) or soft tissue. Muscle tension headache often starts at the base of the skull and can extend over the entire head, following the occipital-frontal aponeurosis. Temporal arteritis, temporomandibular joint (TMJ) disease, dental infections, and sinus infections frequently have a highly localized area of discomfort. Meningitis, encephalitis, SAH, and even severe migraine, although intense in nature, are usually more diffuse in their localization.

5. The character of the pain (eg, throbbing, pressure), although sometimes helpful, may not be adequate to differentiate one type of headache from another.

6. The location of head pain at onset and as the pain progresses is helpful when the patient can identify a specific area. It is certainly useful to direct the examination to evaluate for externally visible contributing factors, such as an infectious process.

of pain in the ED, either from time or therapy, should not be relied on to rule out serious causes of headache.2

Emergent Causes of Headache and Associated Risk Factors

1. Carbon monoxide poisoning
   a. Breathing in enclosed or confined spaces with engine exhaust or ventilation of heating equipment
   b. Multiple household members with the same symptoms
   c. Wintertime and working around machinery or equipment producing carbon monoxide (eg, furnaces)
2. Meningitis, encephalitis, abscess
   a. History of sinus or ear infection or recent surgical procedure
   b. Immunocompromised state
   c. General debilitation with decreased immunologic system function
   d. Acute febrile illness—any type
   e. Extremes of age
   f. Impacted living conditions (eg, military barracks, college dormitories)
   g. Lack of primary immunization
3. Temporal arteritis
   a. Age >50
   b. Females more often than males (4:1)
   c. History of other collagen vascular diseases (eg, systemic lupus)
   d. Previous chronic meningitis
   e. Previous chronic illness, such as tuberculosis, parasitic or fungal infection
4. Glaucoma—acute angle closure
   a. Not associated with any usual or customary headache patterns
   b. History of previous glaucoma
   c. Age >30
   d. History of pain increasing in a dark environment
5. Increased intracranial pressure
   a. History of previous benign intracranial hypertension
   b. Presence of cerebrospinal fluid (CSF) shunt
   c. History of congenital brain or skull abnormalities
   d. Female gender
   e. Obesity
6. Cerebral venous sinus thrombosis
   a. Female gender
   b. Pregnancy, peripartum, hormone replacement therapy or oral contraceptive use
   c. Prothrombotic conditions
7. Reversible cerebral vasconstriction syndrome
   a. Episodic sudden severe pain, with or without focal neurological findings or seizure
   b. Recurrent episodes over a period up to several weeks
   c. Exposure to adrenergic or serotoninergic drugs
   d. Postpartum state
8. Intracranial hemorrhage (ICH)
   a. Subarachnoid hemorrhage (SAH)
      i. Sudden and severe pain; “worst headache of life”
      ii. Acute severe pain after sexual intercourse or exertion
      iii. History of SAH or cerebral aneurysm
      iv. History of polycystic kidney disease
      v. Family history of SAH
      vi. Hypertension—severe
      vii. Previous vascular lesions in other areas of the body
      viii. Young and middle-aged
   b. Subdural hematoma
      i. History of alcohol dependency with or without trauma
      ii. Current use of anticoagulation
   c. Epidural hematoma
      i. Traumatic injury
      ii. Lucid mentation followed by acute altered mentation or somnolence
      iii. Anisocoria on physical examination

7. Exacerbating or alleviating factors may be important. Patients whose headaches rapidly improve when they are removed from their environment or recur each time they are exposed to a particular environment (eg, basement workshop) may have carbon monoxide poisoning. Most other severe causes of headache are not rapidly relieved or recovered when patients get to the ED. Intracranial infections, dental infections, and other regional causes of headache do not tend to be improved or alleviated before therapy is given.

8. Associated symptoms and risk factors may relate to the severity of headache but rarely point to the specific causes (Box 17.1). Nausea and vomiting are nonspecific symptoms seen in both primary and secondary headaches, but they are rare in simple muscle tension headache. Migraine headaches, increased intracranial pressure, temporal arteritis, and glaucoma can all manifest with severe nausea and vomiting, as can some systemic viral infections with headache. Such factors may point toward the intensity of the discomfort but are not specific in establishing the diagnosis. Immunocompromised patients are at risk for unusual infectious causes of headache, which may present with deceptively low grade symptomatology. Toxoplasmosis, cryptococcal meningitis, and abscess are very rare but may be seen in patients with a history of human immunodeficiency virus (HIV) or other immunocompromised state. This subset of patients may have a serious central nervous system infection without typical signs or symptoms of systemic illness (eg, fever and meningismus).

Another special population to consider is the pregnant and peripartum woman, in whom preeclampsia, idiopathic intracranial hypertension (IIH), and reversible cerebral vascular syndrome should be considered, as well as the even more serious causes of headache including venous sinus thrombosis, pituitary apoplexy, cervical artery dissection, and stroke. Patients on medications containing estrogen are also at higher risk for thrombotic events, such as cavernous venous thrombosis, and this should be considered in the differential diagnosis.

9. A prior history of headache, although helpful, does not rule out current serious problems. One important consideration is the association of migraine headaches and stroke, with particular consideration of carotid dissection. Previous evaluation for serious disease can be useful to guide the current evaluation. Prior visits to an ED or outpatient setting, computed tomography (CT), magnetic resonance imaging (MRI), and other forms of testing can provide support for, or help rule out, a specific diagnosis. Patients with migraine, cluster, and tension headaches tend to have stereotypical recurrent patterns. Adherence to these patterns is also helpful in deciding the degree to which a patient’s symptoms are pursued.

Signs
There are signs that may be elicited on physical examination that can be particularly high yield. For example, deficits of extraocular movements localizing to cranial nerves (CNs) III, IV, and VI may indicate the presence of increased intracranial pressure due to mass lesion or IIH. When headache is associated with an acutely red eye, this finding should prompt consideration of acute angle closure glaucoma and further investigation with testing of...
intraocular pressure. Any focal neurological deficit found on examination, regardless of subtlety, warrants further investigation. Not all signs associated with headache contribute greatly to final determination of diagnosis, but they may serve as cues for further consideration of a serious intracranial process. Nausea and vomiting are often associated with migraine, but they are also associated with intracranial mass, acute angle closure glaucoma, intracranial bleeding, and carbon monoxide poisoning. Additional physical findings associated with various forms of headache are listed in Table 17.3.

### Ancillary Testing

The vast majority of headache patients do not require additional testing (Table 17.4). Advanced imaging should be directed toward the specific disease of concern in the differential diagnosis and not in the measurement of intraocular pressure. Any focal neurological deficit found on examination, regardless of subtlety, warrants further investigation. Not all signs associated with headache contribute greatly to final determination of diagnosis, but they may serve as cues for further consideration of a serious intracranial process. Nausea and vomiting are often associated with migraine, but they are also associated with intracranial mass, acute angle closure glaucoma, intracranial bleeding, and carbon monoxide poisoning.

as a default process in the investigation of headache in general. For example, a head CT scan is not indicated for muscle tension headache or recurrent migraine, and it may not be sufficient to assess for cerebral venous thrombosis or for a posterior circulation stroke. A CT scan performed within 6 hours of onset of headache has been shown to be sufficiently sensitive to exclude the diagnosis of SAH when using a third-generation CT scanner. Outside this window, sensitivity declines, and additional testing must be undertaken for appropriate evaluation for SAH.

Lumbar puncture (LP) with measurement of the opening pressure and cerebrospinal fluid (CSF) analysis is indicated when assessing for an infectious process, such as meningitis or encephalitis, IIH, or SAH. Although evidence for this is scant, it is widely believed that LP may increase the likelihood of herniation in certain cases with elevated intracranial pressure caused by a mass lesion. This is the genesis of the common dictum of “CT before LP” when a mass lesion or abscess is a consideration. In reality, this concern is likely misguided, and the compelling reason to obtain a CT scan first in such patients is that it may provide the diagnosis and make the LP unnecessary.

**DIAGNOSTIC ALGORITHM**

Key elements of the history of present illness, past medical history, and examination are used to narrow the differential diagnosis and choose the appropriate diagnostic pathway. Figure 17.1 outlines a diagnostic algorithm for assessment of headache patients.

![Fig. 17.1. Evaluation algorithm for presentation of headache. CO, Carbon monoxide; CT, computed tomography; H&P, history and physical examination; HA, headache; LP, lumbar puncture; SAH, subarachnoid hemorrhage.](image-url)
immediate management pending completion of a full diagnostic evaluation.

For purposes of the initial assessment, headache can be divided into two categories: (1) accompanied by altered mental status and (2) without altered mental status. Whenever a patient's mental status is impaired, brain tissue is initially assumed to be

### EMPIRICAL MANAGEMENT

Headache, although a frequent chief complaint, is a nonspecific symptom. The speed and intensity of the initial evaluation and treatment are guided by the presentation and the patient's mental status. **Figure 17.2** represents a management algorithm with immediate management pending completion of a full diagnostic evaluation.

For purposes of the initial assessment, headache can be divided into two categories: (1) accompanied by altered mental status and (2) without altered mental status. Whenever a patient's mental status is impaired, brain tissue is initially assumed to be

compromised. The principles of cerebral resuscitation address the seven major causes of evolving brain injury: (1) lack of substrate (glucose, oxygen), (2) cerebral edema, (3) intracranial mass lesion, (4) endogenous or exogenous toxins, (5) metabolic alterations (fever, seizure), (6) ischemia, or (7) elevated intracranial pressure.

Pain is mitigated as soon as possible. The pain medication of choice depends on the working diagnosis of the patient’s headache. For nonspecific mild to moderate headache, oral nonsteroidal antiinflammatory medication is appropriate in analgesic doses (eg, 500 mg of naproxen). Opioids are not first-line management for any type of headache pain, except when ICH (including SAH) is thought to be present.

Other than symptomatic relief of pain, empirical treatment does not precede diagnostic studies in most cases, because the treatment must be targeted to the specific cause of the headache. A significant exception to this is when bacterial meningitis is a consideration. Treatment of bacterial meningitis is time-sensitive, and empirical antibiotics should be administered as soon as possible and before results are available to confirm the diagnosis.

**Disposition**

Patients who are not thought to have a serious cause for their head pain requiring hospitalization but who are without a specific diagnosis are provided with appropriate return precautions and recommendations for follow-up care. Some patients many benefit from beginning a headache journal to facilitate further outpatient evaluation.

**KEY CONCEPTS**

- When a patient with a known headache disorder presents with a change in the pattern of the headache, evaluate for potential serious causes.
- The physical examination in the headache patient focuses on cranial nerves (CNs) II, III, IV, and VI.
- Opioid medication is almost never the analgesic of choice for headache. Simple headache is treated with nonsteroidal analgesic medication, and specific antimigraine therapies are used for migraine.
- Most patients with headache do not require neuroimaging. When obtained, neuroimaging should be tailored to the specific elements of the differential diagnosis of concern.
- The differential diagnosis of sudden severe headache includes subarachnoid or other intracranial hemorrhage (ICH), cerebral venous thrombosis, and cervical artery dissection.
- In those patients for whom there is concern for subarachnoid hemorrhage (SAH), a normal head CT scan obtained using a high resolution scanner within 6 hours of onset is sufficient to rule out SAH. Patients outside this window require lumbar puncture (LP) to achieve appropriate sensitivity in the evaluation.
- Antibiotics should be given prior to LP being performed when bacterial meningitis is suspected.

CHAPTER 17: QUESTIONS & ANSWERS

17.1. The most appropriate initial evaluation of a patient with nontraumatic headache is:
   A. CT scan of brain
   B. EEG
   C. MRI scan of brain
   D. Thorough neurological evaluation
   E. Trial of NSAIDs for pain relief

   Answer: D. A thorough neurological examination may reveal deficits not seen on gross evaluation, prompting expansion of the differential diagnosis to include more concerning etiologies. Depending on the history and remainder of the physical, a normal neurological examination may be reassuring and obviate need for advanced imaging studies.

17.2. In the setting of headache, the presence of nausea and vomiting are diagnostic of which of the following as an underlying cause?
   A. Glaucoma
   B. Increased intracranial pressure
   C. Migraine
   D. Temporal arteritis
   E. None of the above

   Answer: E. Nausea and vomiting are completely nonspecific. Migraine headaches, increased intracranial pressure, temporal arteritis, and glaucoma can all be manifested by severe nausea and vomiting, as can some systemic viral infections with headache. Such factors may point toward the intensity of the discomfort but are not specific in establishing the diagnosis.

17.3. Which of the following causes of headache has a constellation of risk factors that include age older than 50 years, female gender, history of lupus, and previous chronic meningitis?
   A. Abscess
   B. Encephalitis
   C. Increased intracranial pressure
   D. SAH
   E. Temporal arteritis

   Answer: C. A history of polycystic kidney disease is a risk factor for SAH. Other historical details and risk factors for SAH are sudden severe pain, acute severe pain after sexual intercourse or straining, history of SAH or cerebral aneurysm, family history of SAH, severe hypertension, previous vascular lesions in other areas of the body, and being young or middle aged.

17.4. A history of polycystic kidney disease is an associated risk factor for which of the following potentially catastrophic causes of headache?
   A. Cerebral venous sinus thrombosis
   B. Increased intracranial pressure
   C. SAH
   D. Subdural hematoma
   E. Temporal arteritis

   Answer: C. A history of polycystic kidney disease is a risk factor for SAH. Other historical details and risk factors for SAH are sudden severe pain, acute severe pain after sexual intercourse or straining, history of SAH or cerebral aneurysm, family history of SAH, severe hypertension, previous vascular lesions in other areas of the body, and being young or middle aged.
CHAPTER 18

Diplopia

Kama Guluma

PERSPECTIVE

Epidemiology

Diplopia, or double vision, is of two types, monocular and binocular. For patients who present to the emergency department (ED) with diplopia, most cases are binocular, with cranial nerve (especially sixth nerve) palsies being among the most common causes. The remainder (=15%) are monocular.

Pathophysiology

Monocular diplopia, or double vision that persists in one affected eye, even with the other one closed, is an ophthalmologic problem related to distortions in the light path. Binocular diplopia, or double vision that resolves when either eye is closed, is the result of a misalignment in the visual axes and has a wide range of causes. These can be organized in a progression from the eye distally to the brainstem proximally. The process responsible might involve oculomotor muscle dysfunction, cranial nerve (CN) dysfunction, or intranuclear or supranuclear lesions in the brainstem or above. In a recent, prospective observational study of 260 ED patients presenting with binocular diplopia, a secondary cause of the diplopia was delineated in 36% and, of these, the most frequent diagnoses were stroke (45%), multiple sclerosis (18%), brain tumors (12%), and cerebral aneurysms (8%).

DIAGNOSTIC APPROACH

Differential Considerations

The causes of diplopia are myriad, ranging from relatively benign to significantly pathologic. The clinical approach in the ED entails sorting out those that may result in rapid and profound morbidity from those that are less acute. Table 18.1 outlines some key causes of diplopia prioritized by immediate acuity, with mechanism and distinguishing features.

Binocular diplopia may be due to a mechanical orbitopathy, a palsy of one or more of the oculomotor cranial nerves, a proximal neuroaxial process involving the brainstem and related cranial nerves, or a systemic neuromuscular process.

Monocular diplopia is an ophthalmologic problem related to distortions in the light path from dry eyes, a corneal irregularity, cataract or lens dislocation or, rarely, from retinal wrinkles involving the macula.

A restrictive mechanical orbitopathy can be caused by orbital myositis, trauma, or infection (abscess), or from craniofacial masses, any of which can directly restrict movement of a single eye. A restrictive orbitopathy is identified by characteristic symptoms and signs combined with the absence of any other focal neurologic deficits. Often involving only a single extraocular muscle, orbital myositis may be a manifestation of a variety of steroid-responsive conditions such as Wegener’s granulomatosis, giant cell arteritis, systemic lupus erythematosus, dermatomyositis, sarcoidosis, rheumatoid arthritis, or idiopathic orbital inflammatory syndrome (orbital pseudotumor).

Graves’ orbitopathy is the most common cause of ocular myopathy in older adults, will affect at least 50% of patients with Graves’ disease, and is bilateral in at least 85% of cases. The patient presenting with thyroid-related diplopia will likely have a preexisting diagnosis of Graves’ disease, but may present with isolated diplopia prior to the onset of systemic symptoms (and diagnosis).

The oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) cranial nerves innervate the muscles that move the eye. With regard to an oculomotor cranial nerve palsy, CN VI is the most commonly affected, followed by CN III, and then CN IV. An isolated simple mononeuropathy in CN III, IV, or VI may be from a demyelinating process (eg, multiple sclerosis), hypertensive or diabetic vasculopathy, or compression. Each nerve has characteristic predilections to which it is vulnerable. In adults, CN III is usually affected by diabetic or hypertensive vasculopathy. Aneurysms in the posterior communicating (most common), basilar, superior cerebellar, posterior cerebral, and cavernous internal carotid arteries are a close second. CN IV is usually affected by trauma from abutting against the tentorium, typically not an isolated symptom or finding, followed by vascular causes. Due to its length, CN VI is the most common nerve to be affected by tumors, elevated intracranial pressure, and microvascular ischemia.

A cavernous sinus infection, mass, or vasculitis may affect CN III, IV, and VI simultaneously (orbital apex syndrome), but typically affects CN VI first because it traverses through the cavernous sinus, as opposed to within its wall, like CNs III and VI. Causes include carotid-cavernous fistula, inflammatory vasculitides such as giant cell arteritis, Tolosa-Hunt syndrome (a rare idiopathic vasculitis), or tumor or infiltration (eg, lymphoma, sarcoidosis) in the orbital apex. A complex palsy in the cavernous sinus may also be iatrogenic due to intravascular injection or diffusion of anesthetic along tissue planes into the pterygoid venous plexus from an intraoral dental anesthetic nerve block. Herpes zoster opthalmicus is a well-described cause of orbital apex syndrome.

A focal brainstem lesion may be from multiple sclerosis (as a clinically isolated syndrome, of which 68% manifest as diplopia). A more diffuse but localized brainstem process may be caused by brainstem tumor, brainstem lacunar stroke, impending basilar artery thrombosis, vertebral artery dissection, or ophthalmoplegic migraine. A vertebral artery dissection may present with diplopia alone, as can an impending basilar artery thrombosis, which can also result in a coma.

A more diffuse process involving the brainstem and/or CNs III, IV, and VI may be infectious, autoimmune, neurotoxic, or metabolic, and involve other neurologic structures, resulting in additional symptoms and signs. Possibilities include basilar meningocerebralitis (cryptococcal, carcinomatous, or viral), at times with the diplopia being the only symptom, botulism, an autoimmune process such as Miller-Fisher or Guillain-Barré syndrome, and Wernicke’s encephalopathy, in which the ophthalmologic manifestations are due to metabolically induced lesions in the pontine tegmentum, abducens nucleus, and oculomotor nucleus.
CHAPTER 18  Diplopia

Pivotal Findings

There are four aspects of questioning the help formulate the differential diagnosis in diplopia: (1) timing of onset and symptoms; (2) directionality and orientation of the diplopia; (3) presence of pain; and 4) presence of other associated symptoms. In terms of the timing of onset, a truly sudden onset suggests an ischemic cause, cerebrovascular or microvascular, especially if the intensity or degree of diplopia was maximal at onset. A fluctuation of symptoms over time may suggest transient ischemic attacks or an impending stroke, but more generally implies a neuromuscular disease. Regarding the directionality of the diplopia, the

</table>

Snake envenomations and tick paralysis can, on rare occasions, present with isolated diplopia, with diplopia being an early and frequent manifestation of neurotoxicity from certain snake venoms. Diplopia may also be part of a paraneoplastic syndrome, but the prototypical neuromuscular cause of diplopia is myasthenia gravis. The initial symptoms are ocular in 85% of myasthenia cases, due to diplopia in 14% of cases. In addition, the symptoms of myasthenia gravis are solely ophthalmologic in almost 20% of patients. However, patients with myasthenia will typically present with diplopia in the setting of a preestablished diagnosis, which facilitates a determination, if not immediate recognition, of the cause.
directions of gaze that elicit or worsen the diplopia and the general orientation of that diplopia—that is, horizontal, vertical, torsional—should be carefully determined to localize the problem. Finally, symptoms associated with the diplopia (eg, pain, neurologic or neuromuscular symptoms) are critical to forming a differential diagnosis, if not making the diagnosis. The presence of pain suggests an inflammatory or infectious process and narrows the differential significantly.

The patient complaining of diplopia should have a thorough neurologic examination, with attention to the cranial nerves and an evaluation of the six cardinal movements of gaze. Each extraocular muscle (and the nerve that supplies it) has a maximal action in a specific direction, and the evaluation of gaze should therefore specifically follow the configuration of a six-limbed asterisk, or an H (Fig. 18.1). The patient should also undergo a careful pupillary and facial examination, looking for signs of pupillary asymmetry, ptosis, lid lag, conjunctival injection or chemosis, periorbital swelling, or proptosis and overall head positioning.

The acuity of onset and presence or absence of pain can be used to prestratify diagnostic possibilities, as shown in Fig. 18.2, especially with regard to vascular, potentially ischemic events.

Symptoms

**Monocular Cause.** This is present only if the patient complains that the diplopia persists in the affected eye with the normal eye closed.

**Mechanical Orbitopathy.** A structural restriction of motion of a single eye, typically gradual in onset, may cause diplopia in a single or multiple directions of gaze, depending on the type and extent of muscular involvement. A sensation of mass effect, discomfort, or pain in the culprit eye is a characteristic symptom. If directions of gaze that elicit or worsen the diplopia and the general orientation of that diplopia—that is, horizontal, vertical, torsional—should be carefully determined to localize the problem. Finally, symptoms associated with the diplopia (eg, pain, neurologic or neuromuscular symptoms) are critical to forming a differential diagnosis, if not making the diagnosis. The presence of pain suggests an inflammatory or infectious process and narrows the differential significantly.

The patient complaining of diplopia should have a thorough neurologic examination, with attention to the cranial nerves and an evaluation of the six cardinal movements of gaze. Each extraocular muscle (and the nerve that supplies it) has a maximal action in a specific direction, and the evaluation of gaze should therefore specifically follow the configuration of a six-limbed asterisk, or an H (Fig. 18.1). The patient should also undergo a careful pupillary and facial examination, looking for signs of pupillary asymmetry, ptosis, lid lag, conjunctival injection or chemosis, periorbital swelling, or proptosis and overall head positioning.

The acuity of onset and presence or absence of pain can be used to prestratify diagnostic possibilities, as shown in Fig. 18.2, especially with regard to vascular, potentially ischemic events.

Symptoms

**Monocular Cause.** This is present only if the patient complains that the diplopia persists in the affected eye with the normal eye closed.

**Mechanical Orbitopathy.** A structural restriction of motion of a single eye, typically gradual in onset, may cause diplopia in a single or multiple directions of gaze, depending on the type and extent of muscular involvement. A sensation of mass effect, discomfort, or pain in the culprit eye is a characteristic symptom. If
the cause is infectious, the patient may have a history of a fever. Diplopia that is worse in the morning suggests Graves’ myopathy, presumably due to the venous congestion of the ocular muscle associated with being supine.

**Isolated Oculomotor Nerve Palsy.** The patient with a CN III palsy typically reports diplopia in all directions of gaze, except on lateral gaze to the affected side. A CN IV palsy resulting in rotational double vision makes descending stairs, reading, and watching television in bed difficult. Diplopia that worsens on lateral gaze to one direction implies an issue with CN VI on that side. A patient with diplopia from an isolated palsy of CN III, IV, or VI will typically not have other associated symptoms. Pain and speed of onset are differentiators; a sudden isolated CN III, CN IV, or CN VI palsy associated with orbital discomfort in a patient with chronic diabetes or hypertension strongly suggests that microvascular ischemia is the cause, with a caveat that with a CN III palsy, a headache frequently accompanies aneurysmal compression.23

The diplopia from a problem involving the cavernous sinus or orbital apex, unlike an isolated mononeuropathy, may manifest as a combination of any of the gaze abnormalities noted above, because more than one cranial nerve may be involved. It may be gradual in onset and associated with retroorbital pain or blurred vision due to venous congestion. Because branches of the trigeminal nerve travel through the orbital apex, the patient may have associated ipsilateral periorbital facial numbness or dysthesia.

**Neuroaxial Process Involving the Brainstem and Related Cranial Nerves.** A focal brainstem lesion (eg, in multiple sclerosis) may result in isolated diplopia. However, localized brainstem lesions such as those from mass effect or ischemia typically also result in so-called neighborhood symptoms and signs from anatomically contiguous involvement, of which double vision may be the most prominent and therefore the presenting complaint (see Box 18.1). It is therefore important to screen for those other symptoms and signs actively. Additional symptoms of nausea, vertigo, or slurred speech are concerning for an impending basilar artery occlusion, especially if symptoms are sudden in onset, painless, and fluctuate, or a brainstem mass, if gradual in onset and progressive over days. A young person with an ophthalmoplegic migraine may present in a similar fashion to someone with a brainstem stroke but will typically develop an associated ipsilateral headache.

Diplopia from a more diffuse neurologic syndrome that happens to involve the brainstem and cranial nerves is usually gradual in onset and manifests with various other discordant symptoms. A gradually evolving combination of double vision, slurred speech, and problems swallowing suggests foodborne botulism, especially if additional symptoms of dry mouth, nausea, and diffuse muscle weakness are present. Double vision, clumsiness, and altered mentation in a patient with chronic alcoholism, malnutrition, or history of bariatric surgery should raise the possibility of Wernicke’s encephalopathy. Diplopia and other cranial nerve symptoms, together with headache, photophobia, stiff neck, and/or fever, are suspicious for a basilar meningoencephalitis.

**Neuromuscular Disorder.** Diplopia that is variably triggered in multiple directions, and without a distinct structural or neurologic cause evident, implies a neuromuscular cause such as myasthenia gravis. A mild neuromuscular manifestation of myasthenia may present with a diplopia isolated to one direction, however. Diplopia from neuromuscular disease generally fluctuates over time and, in myasthenia gravis, worsens with fatigue and improves with rest.24 There may be associated symptoms of proximal muscle weakness (eg, difficulty holding arms above the head or climbing stairs), shortness of breath, or difficulty swallowing.

**Signs**

*Monocular Cause.* With monocular diplopia—typically a problem with abnormal refraction—the diplopia from the affected eye should resolve when a pinhole is used, unless it is due to a retinal abnormality.

**Mechanical Orbitopathy.** Signs of a structural orbitopathy or myositis include proptosis, periorbital swelling, edema, conjunctival or scleral hyperemia, and palpebral swelling involving a single eye. Diplopia due to a mass in the orbit may appear as a clean, ordinal mechanical diplopia, in which having the patient attempt to look in the direction of the problem induces the most diplopia, with an axis of visual image separation parallel to the direction of the gaze (as can at times be seen in patients with significant periorbital swelling from trauma). In contrast, diplopia due to a process in any of the individual extraocular muscles, except for the lateral or medial recti muscles, may present in a messy eccentric or torsional manner based on the direction of pull of the individual muscle or muscles. In patients with thyroid-related diplopia, the signs induced on testing extraocular eye movements will not reflect the stereotyped deficits typical of palsies of the oculomotor cranial nerves. Ocular myositis can be distinguished from a neuromuscular palsy in that it abruptly restricts eye movement away from the muscle, whereas a cranial nerve palsy smoothly and progressively impairs movement toward the weakened muscle. Stigmata of Graves’ disease include lid lag, diffuse conjunctival edema, and vascular injection and, because it typically affects the inferior and medial recti muscles first, restriction of elevation and abduction of the eye. Patients with thyroid-related diplopia may tilt their head back to accommodate for the restriction of upward gaze by the thickened inferior rectus muscle.

**Isolated Oculomotor Nerve Palsy.** Palsies from an isolated mononeuropathy of the oculomotor nerve will present with typical findings, as outlined in Fig. 18.3. CN III also innervates the levator palpebrae superioris muscle, which lifts the upper eyelid, and provides parasympathetic innervation to two intrinsic ocular muscles, the ciliary and constrictor pupillae muscles, which

constrict the pupil. An isolated CN III palsy presents with diplopia in all directions of gaze, except on lateral gaze to the affected side and an eye that is deviated down and out, with a dilated pupil, and ptosis. Typically seen in older patients with vascular risk factors such as diabetes and hypertension, diplopia due to microvascular ischemia may present with an isolated CN III palsy associated with pain, classically sparing the pupil, whereas that from compression (ie, from an aneurysm) is associated with pupillary mydriasis due to compression of pupillomotor parasympathetic fibers in the exterior of the nerve. The so-called rule of the pupil—more of a guideline than a rule—states that an otherwise complete CN III palsy (complete ptosis, completely down and out), with normal pupillary size and reactivity, rules out compression as the source. However, the presence of pupillary involvement does not rule in mechanical compression as the cause. A large case series of patients with CN III palsies revealed that over 50% of patients with diabetic microvascular ischemia had pupillary involvement, possibly from concomitant autonomic neuropathy, although pain was more common with CN III palsies from aneurysms (94% of cases) than from diabetic microvascular ischemia (69% of cases). A rotational diplopia that worsens on looking down and toward the nose implies a superior oblique (CN IV) palsy. An abducens nerve (CN VI) palsy may present with bilateral findings, because elevated intracranial pressure from a brain tumor or malfunction ventriculoperitoneal shunt may be the cause.

In contrast to a mononeuropathy, the combination of ipsilateral palsies of CN III, IV, and VI from an orbital apex or cavernous sinus process will typically present with additional findings— together called orbital apex syndrome—of exophthalmos, chemosis, and injection. Sensory deficits corresponding to the ophthalmic (V1) and maxillary (V2) divisions of the trigeminal nerve may be present, given their course through the orbital apex.

**Fig. 18.3.** Corresponding muscle dysfunction, symptoms and examination findings for each oculomotor cranial nerve palsy. CN, Cranial nerve.
ophthalmoplegia. Most patients with Wernicke’s encephalopathy have ocular abnormalities, including nystagmus and ophthalmoplegia (usually from a CN VI palsy), typically associated with the classic triad of nystagmus, altered mental status, and ataxia. A fever suggests the possibility of an infectious process such as basilar meningoencephalitis.

**Neuromuscular Disorder.** The stigmata of neuromuscular disease such as muscle atrophy or weakness may be apparent on physical examination. Patients with myasthenia gravis may have unilateral or bilateral ptosis, weakness on forced eyelid closure, and generalized muscle weakness, but with normal reflexes and no sensory abnormalities. About 50% present with isolated ocular abnormalities. The diplopia may represent a myasthenic crisis, possibly associated with occult respiratory muscle weakness and ventilatory insufficiency.

**Ancillary Testing**

The patient with monocular diplopia should undergo a slit lamp and funduscopic examination and may need an evaluation by an ophthalmologist. A monocular cause of diplopia will not typically require an extensive neuroophthalmologic evaluation.

In the patient with a suspected or evident mechanical orbitopathy, a magnetic resonance imaging (MRI) scan of the orbits with gadolinium can allow an assessment for enlargement or enhancement in extraocular muscles and orbital structures, although a contrast-enhanced cranial computed tomography (CT) scan with fine cuts through the orbit can be used as a second-line option. The same imaging paradigm applies to localization of the process within the cavernous sinus or orbital apex, because it will highlight infiltrative, inflammatory, or compressive pathology.

For an isolated neuropathy of CN III, IV, or VI presenting without evidence of an aneurysm, the optimal study is MRI of the brain and orbits with gadolinium, high-resolution cuts through the brainstem, and fat-suppressed orbital imaging to assess for inflammation, neoplasm, or demyelination along the course of the nerves. If an aneurysm is suspected, the imaging modality chosen (typically magnetic resonance angiography [MRA] and CT angiography) should be standard for that required to assess for an aneurysm; this is detailed in other chapters in this text specifically devoted to the topic.

If myasthenia gravis is suspected, a bedside test that can be performed is the ice test. An ice-filled glove or bag is applied to the patient’s closed eye or eyes, held there for about 5 minutes, withdrawn, and any improvement in ptosis (typically ≥3 mm) or diplopia noted. Cold temperatures mitigate the effect of myasthenia-related acetylcholine receptor blockade by decreasing cholinesterase activity and promoting the efficacy of acetylcholine at the endplate. The bedside tests with the highest sensitivities for ocular myasthenia gravis are fatigability on sustained upgaze (sensitivity, 80%; specificity, 63%) and the ice test (sensitivity, 80%; specificity, 25%). An edrophonium (Tensilon) challenge can also be performed, if the drug is available.

**DIAGNOSTIC ALGORITHM**

The critical, emergent, and urgent diagnoses applicable to each of the differential considerations noted are outlined in Table 18.1. The refinement of the differential diagnosis for the ED patient with diplopia involves determining the exact nature of the diplopia and functional location of the defect and screening for associated symptoms and findings that may suggest the underlying cause. Most of this diagnostic resolution is done at the bedside, followed by targeted neuroophthalmologic imaging, as indicated. The diagnostic challenge, in a context of cost-effective and efficient resource utilization, tends to be “Where do I look? … and for what? … and with which tool?” This challenge can be addressed, as reflected in the diagnostic algorithm in Fig. 18.4, using a phased systematic approach that incorporates the following queries, taking into consideration the symptoms and signs described earlier (see “Pivotal Findings”):

1. Is the diplopia monocular?
2. Is the diplopia due to a restrictive, mechanical orbitopathy?
3. Is the diplopia due to a palsy of the oculomotor cranial nerves (CN III, IV, VI) in a single eye?
4. Is the diplopia due to a neuroaxial process involving the brainstem and related cranial nerves?
5. Is the diplopia due to a neuromuscular disorder?

The first key assessment is to determine if diplopia is purely monocular. If it is, the evaluation essentially ends with ophthalmologic considerations. In contrast, if the diplopia is determined to be binocular, the next question is whether or not there is a simple mechanical orbitopathy, from an inflammatory, traumatic, neoplastic, or infectious mass effect directly restricting the movement of a single eye. If both eyes are involved, thyroid disease (Graves’ orbitopathy) is a consideration. If an orbital mechanical problem is clearly apparent, with no neuroophthalmologic findings (including ptosis, pupillary abnormality, and anisocoria) or neurologic findings (including cranial nerve abnormalities), the initial evaluation can proceed along these lines.

If the diplopia does not appear to be strictly mechanical, the next question is whether there is a unilateral oculomotor cranial nerve palsy in the oculomotor (CN III), trochlear (CN IV), or abducens (CN VI) nerve, either as an isolated simple mononeuropathy from compression or microvascular ischemia or ipsilateral involvement of more than one of these oculomotor nerves (from mass, inflammation, or infection in the posterior orbit or cavernous sinus; orbital apex syndrome). An older diabetic patient with a classic presentation of mononeuropathy from microvascular ischemia will typically not need neuroimaging because the yield regarding another pathology is very low. If there is any equivocation, however, it would not be unreasonable to pursue this in the ED because a small percentage of patients with risk factors for microvascular ischemia (eg, hypertension, diabetes, smoking) may have a cause other than microvascular ischemia.

Assuming that a unilateral process limited exclusively to the orbit or oculomotor cranial nerves is not clearly identifiable, the next option is a neuroaxial process involving the brainstem and related cranial nerves, as one of the following: (1) a focal lesion in the brainstem (eg, from multiple sclerosis); (2) a more diffuse but still localized brainstem process (eg, from a brainstem tumor, brainstem lacunar stroke, impinging basilar artery thrombosis, vertebral artery dissection, or ophthalmoplegic migraine); or (3) as part of a more diffuse neurologic syndrome involving the brainstem and/or CNs III, IV, and VI due an infectious, autoimmune, neurotoxic, or metabolic process involving other neurologic structures (eg, basilar meningoencephalitis, foodborne botulism, Miller-Fisher or Guillain-Barré syndrome, Wernicke’s encephalopathy). It should be kept in mind that diplopia may be the first, primary, or only symptom of any of these, and that neurologic signs suggesting a focal brainstem process may actually be a mild or early presentation of a diffuse neurologic syndrome.

Finally, if the presentation of the diplopia does not fit into an anatomically congruent process or central nervous system (CNS), a neuromuscular cause such as myasthenia gravis or tick paralysis may be involved.

**EMPIRICAL MANAGEMENT**

Because the treatment of diplopia depends entirely on the cause, there are few primary treatments for diplopia in the ED, as opposed to addressing whatever secondary disorder is causing it. Such approaches are outlined elsewhere in this text.
Fig. 18.4. Algorithm for the diagnostic approach to diplopia in the ED, a guideline. CN, Cranial nerve; CNS, central nervous system; CT, computed tomography; CTA, CT angiography; DSA, digital subtraction angiography (conventional angiography); DWI, diffusion-weighted imaging; gad, gadolinium; High-res, high-resolution; LP, lumbar puncture; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging.
Management Algorithm

Certain emergent therapeutic measures may be indicated in the context of potentially serious underlying causes, as outlined in the algorithm in Fig. 18.5. The priority is to consider imminent threats to CNS tissue viability such as an impending basilar artery thrombosis and then consider rapidly evolving threats to CNS tissue viability such as meningoencephalitis or Wernicke’s encephalopathy and institute indicated treatments empirically as, or even before, the evaluation gets underway.

The patient with diplopia will typically require admission for further evaluation and treatment of the underlying disorder, unless diagnosed with a low-acuity condition such as microvascular ischemia. A CN III or VI palsy from microvascular ischemia is generally self-limited; the pain usually resolves after a few days, and complete spontaneous resolution is the norm, occurring in up to 95% of patients. These patients can typically be discharged home, with close outpatient follow-up.
### KEY CONCEPTS

- Monocular diplopia persists in one affected eye, even with the other one closed. It is an ophthalmologic problem related to refractory distortions in the light path or from buckling of the retina.
- Binocular diplopia resolves when either eye is closed and is the result of a misalignment in the visual axes.
- Four lines of questioning that help formulate the differential diagnosis of binocular diplopia are as follows: (1) cadence of onset and symptoms (a sudden onset suggests an ischemic event; a fluctuation of symptoms suggests transient ischemic attacks, impending stroke, or neuromuscular disease); (2) directionality and orientation of the diplopia (horizontal, vertical, torsional); (3) presence of pain, which suggests an inflammatory or infectious process, and (4) the presence of other associated symptoms, which suggest a larger disease process (eg, infection, CNS ischemia, neuromuscular disease).
- The diagnostic approach to diplopia entails a methodical consideration of (1) a monocular (refractive) problem, which, when excluded, leads to consideration of (2) a simple restrictive, mechanical orbitopathy, which, when excluded, leads to consideration of (3) a palsy of one or more of the oculomotor cranial nerves, and then (4) a more proximal neuroaxial process involving the brainstem and related cranial nerves; if all else is excluded, then (5) a systemic neuromuscular process.
- An isolated CN III palsy presents with diplopia in all directions of gaze, except on lateral gaze to the affected side, and an eye that is deviated down and out, with a dilated pupil, and ptosis. Microvascular ischemia (typically seen in patients with diabetes), classically spares the pupil. A CN IV palsy results in rotational diplopia that worsens on looking down and toward the nose. A CN VI palsy results in diplopia that worsens on lateral gaze toward the problematic side.
- Simultaneous ipsilateral involvement of more than one of the CN III, IV, or VI nerves from mass, inflammation, or infection in the posterior orbit or cavernous sinus (orbital apex syndrome) may cause a combination of palsies and is associated with retroorbital pain or blurred vision due to venous congestion and possibly ipsilateral numbness or dysesthesia from involvement of the ophthalmic (V1) and maxillary (V2) trigeminal branches that travel though the orbital apex.
- Diplopia from a neuroaxial process involving the brainstem and related cranial nerves may present as (1) a focal lesion in the brainstem (eg, from multiple sclerosis), (2) a more diffuse but still localized brainstem process (eg, from a brainstem tumor or lacunar stroke, impending basilar artery thrombosis, vertebral artery dissection, or an ophthalmoplegic migraine), or (3) as part of a more diffuse neurologic syndrome involving the brainstem and oculomotor nerves (eg, from an infectious, autoimmune, neurotoxic, or metabolic process).
- The diplopia in myasthenia gravis is associated with ptosis, gets worse as the patient fatigue, and improves with rest or on placing ice over the eye.
- The empirical treatment of conditions causing diplopia, instituted even before testing for specific entities is begun, is directed toward imminent threats to airway and ventilation (eg, with botulism and myasthenia gravis), immediate threats to CNS tissue viability (eg, with basilar artery thrombosis or stroke), and rapidly evolving threats to CNS tissue viability (eg, with meningoencephalitis or Wernicke’s encephalopathy).

CHAPTER 18: QUESTIONS & ANSWERS

18.1. A 65-year-old man with a long-standing history of diabetes and hypertension presents with sudden onset of persistent diplopia that began a few hours before arrival. He describes left retro-orbital discomfort, and his examination is notable for a left eye that is deviated laterally and downward, with a palsy of movement medially and upward. He also has a left-sided ptosis but no conjunctival injection, chemosis, or proptosis. His pupils are equal in size at 4 mm, round, and equally reactive to light in both a direct and consensual reflex, and his examination is otherwise unremarkable. What is the most likely cause of the diplopia?

A. Brain tumor
B. Cerebral aneurysm
C. Microvascular ischemia
D. None of these
E. Orbital apex syndrome

Answer: C. Based on examination, this is a patient who has a pupil-sparing CN III (third nerve) palsy. Because his pupillary examination is normal, with an otherwise complete CN III palsy, the so-called rule of the pupil applies. The palsy is very unlikely to be due to external compression from a brain tumor, aneurysm, or orbital apex process. It is a typical presentation of microvascular ischemia, to which the patient is predisposed, given his history of diabetes and hypertension.

18.2. A 56-year-old woman presents with recurrent episodes of diplopia that have been ongoing for a week. She describes double vision that gradually comes and goes, typically worse at the end of the day, with no particular direction or orientation to the diplopia. The patient’s coworker, who is present in the emergency department (ED) with her, states that the patient’s eyes “looked droopy” during an animated staff meeting they attended that afternoon but does not change so markedly with activity. Diplopia may be associated with hypothyroidism if it is a presenile entity are her symptoms most consistent?

A. Botulism
B. Hypothyroidism
C. Miller-Fisher syndrome
D. Myasthenia gravis
E. None of the above

Answer: D. The patient and coworker are describing what appears to be an activity-related diplopia, with generalized muscle weakness and lack of other focal symptoms, all very suggestive of a possible neuromuscular process (myasthenia gravis). Miller-Fisher syndrome would not be associated with muscle weakness and would not wax and wane. Botulism would typically have a more progressive course, with other associated bulbar symptoms. Diplopia may be associated with hypothyroidism if it is a presentation of or treatment complication of Graves’ disease but would not change so markedly with activity.

18.3. A 76-year-old man with hypertension, hypercholesterolemia, and diet-controlled diabetes presents with a sudden onset of diplopia that developed 30 minutes before arrival. Medics state that the patient’s wife reported that he suddenly began staggering around the room, unable to bear weight on his left side. On examination, the patient has normal vital signs except for hypotension and tachycardia. He describes left retro-orbital discomfort, and his examination is otherwise unremarkable except for a left-sided ptosis but no conjunctival injection, chemosis, or proptosis. His pupils are equal in size at 4 mm, round, and equally reactive to light in both a direct and consensual reflex, and his examination is otherwise unremarkable. What is the most likely cause of the diplopia?

A. Brain tumor
B. Cerebral aneurysm
C. Microvascular ischemia
D. None of these
E. Orbital apex syndrome

Answer: E. A and B

REFERENCES

Answer: D. The paroxysmal onset of the patient’s symptoms, with focal neurologic symptoms and signs, suggests an ischemic event. His crossed deficits and discrete CN III palsy suggest localization in the brainstem.

18.4. Which constellation of symptoms is most concerning for foodborne botulism?
A. Double vision, headache, and right leg weakness
B. Double vision, left eye discomfort, and periorbital swelling
C. Double vision, neck pain, and vertigo
D. Double vision, nystagmus, and confusion
E. Double vision, slurred speech, difficulty swallowing, and dry mouth

Answer: E. Double vision, slurred speech, difficulty swallowing, and dry mouth would be present with foodborne botulism.

18.5. A 45-year-old man presents with progressively worsening double vision associated with right-sided, retro-orbital pain. His examination reveals mild conjunctival injection of the right eye, palsies of CNs III, IV, and VI on that side, some ptosis, a slightly decreased visual acuity to the right eye compared to the left, and mild sensory loss to the right infraorbital maxillary area. Which of the following initial imaging modalities should be used to evaluate the patient?
A. Computed tomography angiography (CTA) or magnetic resonance angiography (MRA) of the brain and neck
B. Contrast-enhanced CT or magnetic resonance imaging (MRI) of the brain, with fine cuts through the orbit
C. Diffusion-weighted MRI of the brain and brainstem
D. Digital subtraction angiography (DSA)
E. Noncontrast computed tomography of the brain

Answer: B. The combined palsy of multiple oculomotor cranial nerves on one side, with no other neurologic deficits apart from mild facial numbness corresponding to the maxillary branch of the trigeminal nerve, especially with the ocular findings and decreased visual acuity, suggests an orbital apex or cavernous sinus problem. The most optimal study would be that outlined in answer B. The risk in using the studies outlined in the other answers is that pathology might be missed because they are not dedicated to the orbits and cavernous sinus.
PERSPECTIVE

Epidemiology and Pathophysiology

Most eye complaints are not immediately sight-threatening and can be managed by an emergency clinician; however, some require immediate recognition, emergent intervention, and consultation. Ocular injuries are one of the leading causes of visual impairment and blindness worldwide. More patients with postoperative complications can be expected to present to the emergency department (ED) as more outpatient ophthalmological surgeries are performed. Nontraumatic diseases, such as glaucoma and peripheral vascular disease leading to retinal ischemia, are more common with advancing age.

The external and internal anatomy of the eye is depicted in Figure 19.1. The globe has a complex layer of blood vessels in the conjunctiva, sclera, and retina. Redness reflects vascular dilation and may occur with processes that produce inflammation of the eye or surrounding tissues. Eye pain may originate from the cornea, conjunctiva, iris, vasculature, or optic nerve. Each is sensitive to processes causing irritation or inflammation.

DIAGNOSTIC APPROACH

Rapid and accurate triage is the most critical consideration in the approach to the red and painful eye. A few problems should be considered critical, because they can rapidly lead to progressive visual loss without immediate intervention in the ED. Emergent conditions require expeditious triage and treatment. Urgent conditions should be managed in the ED before discharge. The remainder of conditions are those, such as conjunctivitis and spontaneous subconjunctival hemorrhage, where time to treatment has little effect on patient comfort or outcome.

Visual acuity has been called “the vital sign of the eye.” Only a few situations preclude early and accurate visual acuity testing. Patients with complaints of contamination with an acid, alkali, or other caustic substance; sudden visual loss, especially if unilateral and painless; and significant trauma, especially with retrobulbar hematoma causing orbital compartment syndrome, should have only a gross visual acuity examination performed as interventions are simultaneously prepared. When not being actively examined or treated, injured eyes should be protected with a rigid shield to prevent inadvertent pressure that could cause additional damage.

Differential Diagnosis Considerations

The diagnostic approach to the red or painful eye typically begins with categorization into traumatic and nontraumatic causes. Patients almost always can report whether or not their eye was injured, even indirectly, such as injury from reflected sunlight.

Traumatic pain and redness can be caused by caustic fluids and solid materials, low-velocity contact with a host of materials that can fall or be rubbed into the eye, higher velocity blunt-force impacts to the orbit or globe, or potentially penetrating injuries. Caustic contamination is discussed elsewhere. Other traumatic complications that must be considered early in the course of care include retrobulbar hematoma, abscess, or emphysema with orbital compartment syndrome and suspicion of an open globe from either blunt or penetrating trauma.

The first triage question for any eye complaint should be, “Did anything get in your eye?” If so, attempt to identify the nature of the substance or foreign body. Specifically, this question seeks to quickly identify eyes that may have been exposed to a caustic substance. Patients exposed to acids, alkalis, and other caustic substances require rapid decontamination before additional evaluation to potentially prevent permanent loss of visual acuity.

The possibility of an open globe must be considered following any traumatic injury regardless of the mechanism. Findings may be obvious, subtle, or occult. Blunt trauma may frankly rupture the globe. Penetrating trauma can result from obvious causes identified through determining the events leading to injury, but it can also be unknown to the victim, such as walking near a person hammering metal or using a high-speed grinder yet not realizing a tiny ballistic metal fragment may have penetrated the eye.

Causes of nontraumatic pain and redness are diverse but are mostly infectious and inflammatory, although these may be due to processes intrinsic to the globe and adjacent structures or be due to ocular manifestations of systemic illness (eg, giant-cell arteritis). Exposure history and review of systems may be helpful when infection is suspected (eg, concomitant upper respiratory tract infections making a viral etiology of conjunctivitis more likely). Questions related to recent surgery and contact lens wear and cleaning practices should not be overlooked. Therefore, nontraumatic eye complaints typically require a more detailed history than would be necessary following a known injury.

Not all visual disturbances are due to conditions that cause ocular inflammation resulting in pain or redness. One that is critical to identify in the triage process is central or branch retinal artery occlusion. Only a rapid funduscopic examination to identify the problem and immediate intervention will afford even a chance to restore sight. This condition is readily apparent as a diffusely pale retina with indistinct or unseen retinal arteries (Fig. 19.2). Because it does not typically present with either pain or external signs (such as, redness), diagnosis and treatment are detailed in Chapter 61. Diplopia is covered in Chapter 18.

Pivotal Findings

Measurement of the patient’s best corrected visual acuity (ie, with glasses on if available) with each eye individually provides vital information when evaluating eye complaints and may be prognostic in some situations. Only a few situations discussed earlier preclude obtaining visual acuity using a chart. Decreased visual acuity caused by abnormal refraction (eg, chronic myopia) can be detected by using a pinhole device during acuity testing, because central vision remains intact in refraction conditions. If there is a non-refractory problem, such as retinal edema or aqueous hemorrhage causing the acuity deficit, pinhole testing will show no improvement in the (poor) visual acuity.
Symptoms and signs that are more likely to be associated with a serious diagnosis in patients with a red or painful eye are listed in Box 19.1.

**Symptoms**

When the presenting complaint is pain, the first step is to characterize it: itching, burning, dull pain, sharp pain, diffuse, or localized. Two historical factors are particularly important: suddenness of onset and perception of a foreign body. Itching tends to be more often due to irritation by blepharitis, conjunctivitis, or dry eye syndrome. Burning is associated with these conditions and with other mostly superficial problems, such as irritation of a pterygium or pinguecula, episcleritis, or limbic keratoconjunctivitis. A foreign-body sensation, particularly when it can be localized, is a strong indicator of corneal origin to the pain (foreign body, corneal abrasion, ulcer, or viral or ultraviolet keratitis). Sharp pain generally results from abnormalities of the anterior eye, such as corneal origin pain and uveitis. Dull pain, which may be severe, is usually generalized throughout the eye (and may be reported as “headache”). It is typically a manifestation of increased intraocular pressure (IOP) (such as, with acute angle closure glaucoma), vitreous infection (such as, endophthalmitis), or the pain is referred from an extra orbital process (such as, sinusitis, migraine headache, or temporal arteritis). Acute orbital compartment syndrome, caused by retro-orbital hematoma, presents with intense pain and progressive visual loss. These patients often present with head trauma that precludes them reporting pain, emphasizing the importance of physical examination.

Rarely is there a chief complaint of redness that is not accompanied by pain, itching, irritation, or foreign body sensation. Completely asymptomatic “red eye” is almost always a spontaneous subconjunctival hemorrhage, which is benign but often alarming to the patient. Spontaneous subconjunctival hemorrhage may follow coughing or straining, but it most often occurs without any identifiable precipitating event and is simply noticed by the patient when looking in a mirror.

Symptomatic red eye commonly causes bulbar or limbal injection of the conjunctiva. Free blood noted behind the bulbar conjunctiva (ie, subconjunctival hemorrhage) or in the anterior chamber (ie, hyphema) may be spontaneous or post-traumatic. Spontaneous subconjunctival hemorrhage is painless, and the presence of pain raises concern for a more serious cause of the hemorrhage, such as direct globe injury or a retrobulbar process. Hyphema of sufficient size to be noted by the patient or bystander usually presents with pain and blurred vision.

Other subjective findings may be transient and detected only by a thorough history. The patient may have symptoms of lid
swelling, tearing, discharge, crust, and discomfort on blinking, or sensitivity to light. Lid swelling can be caused by inflammatory and noninflammatory processes. Concurrent erythema and tenderness of the lid favors the former. In the absence of trauma or other external irritant (e.g., contact dermatitis from eye makeup), inflammatory processes include primary lid problems, such as hordeolum (i.e., sty) or blepharitis, as well as extension from concomitant conjunctivitis or cellulitis in orbital or periorbital structures. When pain is present, tearing is usually secondary. Discharge and crust are most commonly associated with conjunctivitis, whether allergic, chemical, viral, or bacterial. Blepharitis, dacryocystitis, and canaliculitis are other inflammatory processes that may cause a discharge and subsequent crust.

A history of eyelids sticking together, particularly in the morning, is commonly cited as clinical evidence of bacterial, as opposed to viral, conjunctivitis, but this is unreliable. Even when lid sticking is combined with absence of itch and lack of history of conjunctivitis, large studies have failed to show diagnostic correlation between lid sticking and bacterial infection. Similarly, in the pediatric population (younger than 18 years old), lid sticking plus mucoid or purulent discharge show only fair correlation with proven bacterial infection. The hazards of equating lid sticking with bacterial infection are underscored by the fact that viral conjunctivitis, particularly caused by subtypes of adenovirus, can cause dramatic symptoms with mucopurulent discharge, lid sticking, keratitis symptoms, and lid inflammation. In many studies, lack of viral cultures precludes consideration of copathogens or bacterial culture of nonpathogenic flora.

Additional past ocular history questions are listed in Box 19.2.

**Signs**

A complete eye examination usually includes eight components, although many patients require only a limited or directed eye examination, depending on the presentation. The mnemonic VVEEEP (pronounced “veep”) plus slit-lamp and funduscopic examinations represent these components (Box 19.3). We recommend slit-lamp examination for any complaint involving trauma and for any medical presentation involving foreign-body sensation or alteration of vision. Funduscopic examination is usually pursued if there is visual loss, visual alteration, clouding of vision, or suggestion of serious pathology in the history and initial physical examination. A thorough physical examination can be conducted in the following order.

**Visual Acuity**

The initial determination of a patient’s visual acuity provides a baseline from which deterioration or improvement may be
followed. It is also predictive of functional outcome after ocular trauma. Visual acuity is quantitatively assessed by use of a Snellen chart test at a distance of 20 feet (6 m) or a Rosenbaum chart at a distance of 14 inches. Young patients who cannot yet read letters and numbers should be tested with an Allen chart that depicts easily recognizable shapes. Each eye is tested separately with the opposite eye carefully covered. Patients who present without their prescribed corrective lenses may be evaluated by having them view the chart through a pinhole eye cover, which improves most refractive errors in vision.

If the patient cannot distinguish letters or shapes on a chart, visual acuity must be determined qualitatively. Any printed material suffices. The result may be recorded as, for example, “patient able to read newsprint at 3 feet.” If this is not possible, visual acuity is recorded as:

- Unable/able to count fingers (CF)
- Unable/able to perceive hand motion (HM)
- Unable/able to perceive light (LP)

Visual Field Testing

Confrontation is the most common method of testing visual fields in the ED, but it is unreliable for detection of anything short of an extensive field deficit. On the other hand, visual field examination rarely adds useful information in the evaluation of the acutely red and painful eye. Detection of a scotoma usually represents a retinal problem. However, glaucoma may cause scotomata that can be crescent-shaped, involve just the binasal visual fields, or affect all peripheral vision. Hemi- or quadrantanopia is more commonly a problem of the neural pathways to the brain.

External Examination

Gross abnormalities are assessed by a visual inspection of both eyes simultaneously. Findings may be more apparent if compared with the opposite side. Fractures of maxillofacial bones are associated with ocular injuries, some of which require immediate intervention by an ophthalmologist.

Globe position is part of the external examination. Subtle exophthalmos and enophthalmos are rare and best detected by looking inferiorly, tangentially across the forehead, from over the patient’s scalp. Exophthalmos may have traumatic or nontraumatic causes but is due to increased pressure or a space-occupying lesion within the orbit, which may manifest as pain. Medical causes include cellulitis or intraorbital or lacrimal tumors. Hyperthyroidism may cause enlargement of extraocular muscles.

The most important cause of exophthalmos in the ED is orbital compartment syndrome, which pushes the globe forward, stretching the optic nerve and retinal artery and increasing IOP. The resulting microvascular ischemia is sight-threatening if sufficiently severe and persistent. Orbital emphysema and inflammation caused by a retained foreign body behind the eye are other causes of exophthalmos. Other signs of orbital compartment syndrome include limited eye movement and a relative afferent pupillary defect (RAPD) described under ancillary testing. If retrobulbar hemorrhage is the cause, blood often dissects anteriorly to fill the subconjunctival potential spaces.

The discovery of exophthalmos should prompt ocular tonometry measurements to determine the urgency of intervention. Trauma, particularly penetrating globe injury with extrusion of vitreous, can cause the globe to recede into the orbit, but the most common cause of enophthalmos is actually pseudo-enophthalmos when the contralateral globe is proptotic.

Inspection also involves examination of the upper and lower palpebral sulci for foreign bodies or other abnormalities. The lower sulcus is easily viewed after manual retraction of the lower lid toward the cheek and having the patient gaze upward. The upper sulcus is inspected by pulling its lashes directly forward and looking under the lid with white light. The lid can then be everted by pressing a cotton-tipped applicator in the external lid crease and folding the lid margin over the applicator.

Conjunctivitis, with conjunctival injection and discharge, is a common diagnosis following evaluation of patients with red and painful eyes. The presence of punctate “follicles” (i.e., hypertrophy of lymphoid tissue in Bruch’s glands) along the conjunctival surfaces of one or both lower lids has been touted to be relatively specific for a viral etiology (Fig. 19.3). Indeed, the “typical” viral “pink eye” used to be called acute follicular conjunctivitis. Chlamydia trachomatis, a chronic keratoconjunctivitis caused by Chlamydia trachomatis, is one notable nonviral cause of this follicular hypertrophy.

Any discharge present is assessed as serous, mucoid, or purulent. Both viral and bacterial infection can cause mucoid or purulent discharge, so it is not possible to clinically distinguish viral from bacterial conjunctivitis on this basis alone.

A red eye in a neonate or infant is always abnormal. It is usually caused by corneal abrasion or infection. Corneal abrasions can also be a cause of inconsolable crying in an infant. Fluorescein examination helps to identify traumatic abrasions and herpetic keratitis acquired from the birth canal or transmitted from a caregiver’s fingers.

Extraocular Muscle Function

Limitation of ocular movement in one eye may be detected by having the patient follow the examiner’s finger or a bright light through the cardinal movements of gaze. The eyes may move in a disconjugate fashion, or the patient may admit to diplopia if asked. Diplopia on extreme gaze in one direction may indicate entrapment of one of the extraocular muscles within a fracture site, but more often is caused simply by edema or hemorrhage related to the injury and is functional rather than actual entrapment. In the absence of trauma, diplopia is rarely associated with redness or pain.

Pupillary Evaluation

The pupils are inspected for abnormalities of shape, size, and reactivity. These examinations are conducted with light specifically directed into the pupil and by means of the swinging flashlight test.
Blunt or penetrating trauma, previous surgery (eg, iridotomy for cataract extraction), and synechiae from prior iritis or other inflammatory condition are the most common causes of irregularly shaped pupils.

Asymmetrically sized pupils may represent normal or pathologic conditions. Physiological anisocoria is a slight difference in pupil size that occurs in up to 10% of the population. Topical or systemic medications, drugs, and toxins may cause abnormal pupillary constriction or dilation.

Pathologic reasons for failure of one pupil to constrict with a direct light stimulus include globe injury, abnormalities of afferent or efferent nerves, and paralysis of the ciliaris or sphincter pupillae muscles in the iris. Potentially serious problems, which also cause pain and redness, include uveitis and acute angle-closure glaucoma.

While examining the pupils, the anterior chambers can be visually inspected for hyphema or hypopyon. Blood in the anterior chamber is usually the result of direct ocular trauma and may be associated with traumatic mydriasis or an obvious tear of the iris. If penetration and rupture can be reasonably excluded, the hyphema should be graded and IOP determined. Inability to view posterior structures through the anterior blood may necessitate radiologic or ultrasonographic imaging.

Ancillary Testing

Physical examination can be augmented by a number of additional tests to assess the relative amount of light reaching the retina or being converted into neural signals, determine the IOP, and visually inspect the anterior and posterior globe with magnification. Imaging of internal anatomy and pathology can be accomplished at the bedside or in the radiology suite.

Swinging Flashlight Test

The swinging flashlight test is used to determine whether a RAPD exists (see https://youtu.be/soiKbngQxgw). It is described in Chapter 61. A RAPD may be partial or complete and due to inhibition of light transmission to the retina because of vitreous hemorrhage, loss of some or all of the retinal surface for light contact because of ischemia or detachment, or the presence of lesions affecting the prechiasmal optic nerve (eg, optic neuritis).

Pressure Determination

Ocular tonometry is usually the last examination performed in the ED. Common methods of determining the IOP in the ED include use of electronic, manual (eg, Schiøtz), or applanation tonometers. IOPs in the 10 to 20 mm Hg range are considered normal. Causes of intraocular hypertension include glaucoma in its many forms, suprachoroidal hemorrhage, and space-occupying retrobulbar pathology. Acute angle-closure glaucoma is a relatively rare but an important critical diagnosis to make in the ED. Patients present with pain, the onset of which is often sudden in low-light conditions causing pupillary dilation through contraction and thickening of the iris peripherally. The iris becomes immobile and often irregular, and the pupil is commonly fixed at 5 to 6 mm in diameter. Inability of the pupil to constrict may result in photophobia, and accommodation may be affected. These reactions and the increased IOP can lead to frontal headache, nausea, and vomiting. As inflammation progresses, limbal injection of the conjunctiva is almost universally seen. Figure 19.4 demonstrates many of these findings. Patients presenting with IOPs exceeding 20 mm Hg should have ophthalmological consultation. Rapid treatment is usually not necessary unless the pressure exceeds 30 mm Hg.

Slit-Lamp Examination

The slit lamp is used to examine anterior eye structures. It permits a magnified, binocular view of the conjunctiva and anterior globe for diagnostic purposes and to facilitate delicate procedures. It allows depth perception in otherwise clear structures, such as the cornea, aqueous humor, and lens. Figure 19.5 shows the typical appearance of an angled slit beam reflecting from and passing through the cornea. Components of the slit-lamp examination are found in Box 19.4.

Fluorescein examination with cobalt blue light from the slit lamp identifies corneal defects. Fluorescein is not taken up by intact corneal epithelium but concentrates in areas where corneal epithelium is breached by abrasion, foreign body, or ulcer (Fig. 19.6). If the patient cannot sit in front of a slit lamp, a Wood’s lamp may be used for magnification and an alternative light source instead. When corneal perforation is suggested, Seidel’s test can be used as described in Chapter 61 (see https://www.youtube.com/watch?v=GLFcAv0DR4c).
Ulcers can be large and easy to visualize (Fig. 19.7) or small and difficult to detect. They are best identified under slit-lamp examination by noting a denuding of epithelium with surrounding edema. Edema, in the form of increased interstitial water, is seen as whitish clouding of the normally clear tissue in the base of and adjacent to the lesion. This is best identified without fluorescein staining.

**Direct Funduscopic Examination**

Fundusccopy is used to examine posterior eye structures. Emergency physicians most commonly perform a nondilated funduscopic examination, because there are several eye conditions in which dilation may be harmful (eg, angle-closure glaucoma). Iridodalysis, lens dislocation, and conditions requiring early intervention are usually identifiable along the visual axis. Inability to obtain a red reflex or visualize the fundus of the eye can be due to the causes listed in Box 19.5.

In the absence of trauma, few posterior findings are associated with chief complaints of external redness. Findings associated with visual loss include pallor of the retina indicating ischemia, “cupping” of the optic disk indicating glaucoma, indistinctness of disk margins indicating papilledema or optic neuritis or neuropathy, air or plaque emboli in retinal arteries, and a host of other signs indicating more chronic ocular or systemic pathology not normally amenable to management in the ED.

**Topical Anesthetics**

Relief of discomfort after instillation of a topical anesthetic can be used as a diagnostic test for a superficial source of pain. In general, abolition of pain by local anesthetic drops indicates pain of corneal origin. Modest but incomplete relief suggests a conjunctival process. Intraocular pain, including pain associated with uveitis, is not diminished by local anesthetic solution.

**Imaging**

A penetrating wound that violates the sclera may be immediately obvious. In other cases, the penetration may have occurred elsewhere in the head or neck then reach the orbit posterior to the orbital septum to injure the globe. In these cases, computed tomography (CT) or plain radiography is used to determine the presence of an intraocular or intraorbital foreign body.

Ultrasoundography can be used in the ED when patient condition may preclude movement to the radiology suite, and it can be
highly accurate in identifying ocular foreign bodies. In experienced hands, ultrasonography is an excellent bedside modality for evaluating pathology of the globe. Ultrasonography can be used to evaluate abnormalities of the anterior chamber, iris, ciliary body, lens, vitreous, retina, choroid, posterior wall, and optic nerve.

Although plain radiography may directly identify facial fractures, or indirectly suggest fractures by detecting an air-fluid level in the orbit or fluid in the paranasal sinuses, CT is now considered the preferred modality for evaluating orbital trauma. Magnetic resonance imaging (MRI) clearly delineates orbital and retro-orbital structures but is less rapidly obtained with no advantages over CT in trauma, is contraindicated in cases of suspected metallic foreign body, and is reserved for ocular issues felt to be of neurological origin. All imaging modalities should be considered complementary to each other when employed in appropriate settings.

Laboratory Testing

Laboratory tests, such as a complete blood count, are generally not necessary in the evaluation of the red and painful eye. One notable exception is the evaluation of temporal arteritis. Temporal arteritis may present with eye pain and decreased visual acuity, but there may be no injection or other physical alteration of the eye. An erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are generally elevated in the acute phase, although one or both may be normal in up to 5% of biopsy-proven cases of temporal arteritis. We do recommend obtaining CRP and ESR in cases of suspected temporal arteritis.

Microbiologic cultures are rarely ordered in the ED, but an ophthalmologist may request them in select circumstances.

**DIAGNOSTIC ALGORITHM**

A recommended algorithmic approach to the patient with an acutely red or painful eye is provided in Fig. 19.8.

**Critical Diagnoses**

Critical diagnoses require immediate intervention in the ED. Ophthalmologic consultation is mandatory but should not delay potentially sight-saving procedures. Critical ophthalmologic diagnoses that do not present with redness or pain are discussed in Chapter 61. Because of its prognostic value, a quick visual field test should be obtained while the patient is being triaged and subsequently managed.

Caustic injury to the eye can rapidly lead to a destructive keratoconjunctivitis if the agent is not removed immediately (Fig. 19.9). Intervention is initiated on history alone, before any other examination is performed. Early and copious irrigation is indicated. Many patients have already undergone extensive irrigation at the job site, but when the exposure has occurred in the home, irrigation prior to arrival in the ED is uncommon. Alkaline caustic agents cause a liquefactive necrosis of the cornea by progressively reacting with the corneal layers, and destruction is severe and relentless. Acid injury causes coagulation necrosis, which tends to limit the depth of injury. Both types require copious irrigation with any clean, relatively neutral fluid (eg, tap water, normal saline, and so on). Continuous irrigation until the pH of the tears is neutral is the only effective method to terminate these chemical reactions. A normal pH and post-irrigation examination (except expected conjunctival injection) does not mandate that an ophthalmologist respond to the ED. Any other post-treatment abnormalities do necessitate the presence of an ophthalmologist.

Orbital compartment syndrome can occur whenever intraorbital pressure increases to the point of causing dysfunction of the optic nerve. IOP can be used as a surrogate measure of intraorbital pressure when this can be safely measured. Retrobulbar hematoma is usually caused by orbital trauma, but it can also occur spontaneously in patients with coagulopathy. Retrobulbar abscess or emphysema can also occur. Elevated IOP in any of these conditions implies an orbital compartment syndrome and constitutes a surgical emergency. Intervention in the ED requires decompressing the orbit by performing lateral canthotomy and cantholysis (see https://youtu.be/bUAagMd_q8A) to relieve the pressure on the optic nerve, and should be performed within 2 hours of injury for the best chance of sight recovery. These patients should be examined by an ophthalmologist as soon as possible afterward.

Patients with acute angle closure glaucoma (see earlier) require prompt medical intervention to decrease IOP in the ED and urgent ophthalmologic consultation (see Chapter 61). Follow-up can be decided based on the patient’s response to therapy and discussion with the ophthalmologist.

**Emergent Diagnoses**

Most emergent diagnoses involve some kind of inflammation secondary to trauma, infection, or systemic disease. These include keratitis, anterior uveitis, scleritis, and endophthalmitis. Any of these may be complications of surgical procedures, and an appropriate ophthalmological history must be obtained. Consultation with an ophthalmologist is appropriate for all emergent diagnoses.

If penetrating ocular trauma is confirmed, or if the possibility persists after evaluation, an ophthalmological consultation is indicated.

Keratitis is treated with topical anesthesia, which provides immediate (but temporary) relief of pain, thus reinforcing the corneal origin of the process and facilitating examination and definitive diagnosis.

Following thorough irrigation, thermal and chemical burns must receive a careful slit-lamp examination for potential full-thickness injury. If this is not found, superficial corneal burns may be treated similarly to abrasions. If full-thickness injury is identified, immediate ophthalmological consultation is indicated.

Corneal ulcerations caused by overuse of contact lenses are treated with prophylactic antibiotics and avoidance of the lenses for at least 72 hours. We recommend follow-up with an ophthalmologist or optometrist before contact lens use is resumed.

Infections of the cornea with herpes simplex virus can rapidly lead to opacification and significant visual loss. It is most commonly recognized by a characteristic dendritic pattern of fluorescein pooling under blue light (Fig. 19.10). Anterior uveitis, which includes iritis and iridocyclitis, often occurs secondary to a traumatic injury or infectious process or can be associated with serious systemic immune diseases, such as adult and juvenile rheumatoid arthritis, sarcoidosis, and ankylosing spondylitis. We recommend urgent ophthalmologic evaluation, either in the ED or by immediate evaluation in an ophthalmologic clinic, for these conditions.

Scleritis is commonly idiopathic, but may be associated with a systemic inflammatory process, such as a connective tissue disease, gout, or infection (eg, Lyme disease, syphilis, tuberculosis). Episcleritis is a somewhat more common, superficial, and more benign inflammation. Both are discussed in Chapter 61.

Endophthalmitis usually results from an infection of structures inside the globe. It is most common following penetrating trauma but may begin after hematogenous seeding from a remote or systemic infection, particularly in immunocompromised hosts. Unless it is detected early and is responsive to antimicrobial therapy, endophthalmitis is a devastating process that frequently requires enucleation.
Fig. 19.8. Diagnostic algorithm for red and painful eyes. Numbers next to diagnoses correspond to Table 19.1 for management of each condition. FB, Foreign body.
Urgent Diagnoses

Foreign bodies on the cornea or under the lid are removed, as described in Chapter 61.

Superficial corneal abrasions, once universally patched, are now known to heal spontaneously without need for patching, prophylactic antibiotics, or prophylactic tetanus immunization.

Patients with hyphema are placed with head of bed elevated to 30 degrees, and they receive systemic analgesia and, if required, antiemetics, with emergent ophthalmologic consultation (see Chapter 61). Medications affecting platelet function should be avoided. If the iris is not injured, a long-acting cycloplegic agent (eg, topical homatropine) may be recommended to prevent repetitive motion of the iris. After consultation by ophthalmology, outpatient therapy and follow-up often are sufficient for management with simple (eg, acetaminophen) analgesia for pain. We recommend a rigid shield to protect the eye during sleep, but this should not be worn during the day. Patching is not otherwise needed. The patient should see the ophthalmologist or return to the ED if the patient experiences an increase in pain or decrease in visual acuity.

EMPIRICAL MANAGEMENT

Management of the specific entities listed in the diagnostic algorithm presented in Figure 19.8 is presented in Table 19.1. Specific management of ophthalmologic conditions is also discussed in Chapter 61.

Critical and emergent conditions are treated as described earlier. All other ocular emergencies are generally diagnosable in the ED, and treatment is initiated based on the diagnosis made. Caustic exposures receive copious irrigation, but all chemical or liquid exposures should undergo irrigation unless 1 hour has passed since exposure and the patient is completely asymptomatic at the time of evaluation.

Foreign bodies are removed, along with all fine particulate matter. Irrigation is advisable after foreign body removal if there is suspicion of remaining, very fine, foreign substance. After irrigation, conjunctival injection is common, but symptoms are expected to be mild. Patching is not indicated. Patients with significant symptoms after foreign body removal or with corneal abrasion may benefit from a topical nonsteroidal antiinflammatory analgesic solution or dilute topical local anesthetic drops for 24 hours.8,9

An algorithm for the treatment of acute conjunctivitis is presented in Figure 19.11. We do not recommend topical antimicrobial or corticosteroid treatment for conjunctivitis or keratoconjunctivitis (see Chapter 61). This is an area in which antibiotic misuse is widespread. There is no good medical evidence to support the requirements of most daycare and school facilities to mandate antibiotic treatment for acute conjunctivitis before returning to activities with other children. First, some causes of “pink eye” are not infectious. Second, in patients enrolled in clinical trials for acute infectious conjunctivitis, bacteria continue to be cultured many days after treatment is started, and viruses continue to be shed for 2 weeks or more with or without antibiotics. Unless a patient with conjunctivitis might potentially expose an immunocompromised individual, there is no medical reason not to return to daycare or school with or without treatment. If bacterial, only direct eye-to-hand-to-eye exposure will result in transmission. If viral, others have likely already been exposed. Finally, regardless of etiology, complications in healthy children are extraordinarily rare.10

Topical acyclovir, 3% ointment, is indicated for herpes keratitis, in conjunction with ophthalmologic or infectious disease consultation. Azithromycin is indicated for trachoma, again with consultation.

Topical antimicrobial prophylaxis is similarly not indicated for superficial epithelial defects of the cornea, although this also is
### Table 19.1
Management Algorithm for Red Eyes Extended from Diagnostic Algorithm in Figure 19.8*

<table>
<thead>
<tr>
<th>Potential Diagnosis</th>
<th>Management</th>
<th>Consultation</th>
<th>Disposition</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Caustic keratoconjunctivitis</td>
<td>Immediate and copious irrigation with tap water or sterile normal saline until tear-film pH = 7. Solids: Lift particles out with dry swab before irrigation Acids: Minimum of 2 L and 20 minutes Alkalis: Minimum of 4 L and 40 minutes</td>
<td>Ophthalmologist must come to ED if there is any abnormal visual acuity or objective finding on examination after sufficient irrigation, with exception of expected injection of conjunctiva secondary to treatment.</td>
<td>May discharge only if tear film pH = 7 and no findings on examination except conjunctival injection, then ophthalmologist can reevaluate next day.</td>
</tr>
<tr>
<td>2. Orbital compartment syndrome: Exophthalmos (proptosis), decreased visual acuity, painful or limited ocular mobility, and increased IOP</td>
<td>Measure IOP unless possibility of ruptured globe. IOP &gt;30 mm Hg may require emergent needle aspiration or lateral canthotomy and cantholysis in ED.</td>
<td>IOP &gt;20 mm Hg may be surgical emergency, may add medications used in glaucoma #18 to decrease IOP before decompression in ED. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.</td>
<td>Admit all cases of retrobulbar pathology causing increased IOP. Others might be candidates for discharge depending on cause of problem.</td>
</tr>
<tr>
<td>Retrobulbar hematoma: Occurs due to trauma, coagulopathy, or thrombocytopenia and associated with possible dissection of blood to potential space under bulbar conjunctiva</td>
<td>Hematoma: Correct any coagulopathy or thrombocytopenia.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Retrobulbar emphysema: Occurs with forceful sneeze or occasionally happens spontaneously and associated with possible dissection of air to potential space under bulbar conjunctiva</td>
<td>Emphysema: Antibiotic prophylaxis to cover sinus flora.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Retrobulbar abscess: Occurs with contiguous or occasionally hematogenously disseminated infection and associated with possible dissection of pus to potential space under bulbar conjunctiva</td>
<td>Abscess: Antibiotics as in orbital cellulitis (see #11).</td>
<td></td>
<td></td>
</tr>
<tr>
<td>3. Scleral penetration: Localized redness at site of entry plus possible teardrop pupil, blood in anterior chamber or loss of red reflex</td>
<td>Protect eye from further pressure, provide pain relief, and prevent vomiting. Parenteral antibiotic and tetanus prophylaxis.</td>
<td>Ophthalmologist must come to ED if there is any concern for globe penetration.</td>
<td>Admit for continuation of antibiotics and possible procedural intervention.</td>
</tr>
<tr>
<td>4. Hyphema: Pain, decreased visual acuity, gross or microscopic blood in anterior chamber, may be associated with dilated and fixed pupil following blunt trauma Graded by amount of blood: Percentage of vertical diameter of anterior chamber when blood layers with patient in upright position Microhyphema shows no layering and only suspended red blood cells</td>
<td>First rule out open globe. May require ultrasound if cannot visualize posterior structures. Measure IOP unless possibility of ruptured globe. IOP &gt;30 mm Hg may require acute treatment as in glaucoma (see #18). If IOP &gt;20 mm Hg and no iridodialysis, may use cycloplegic to prevent iris motion.</td>
<td>Discuss findings and use of e-aminocaproic acid and steroids, other medical therapy, best disposition, and follow-up examination by ophthalmologist within 2 days. Some patients may be admitted for observation, bed rest, head elevation, and frequent medication administration.</td>
<td>Most patients can be discharged with careful instructions to return for any increased pain or change in vision. Patients should decrease physical activity and sleep with an eye shield in place. Eyes should be left open while awake so that any change in vision can be immediately recognized. PO NSAIDs or narcotics should be given for analgesia.</td>
</tr>
<tr>
<td>5. Subconjunctival hemorrhage: Red blood beneath clear conjunctival membrane</td>
<td>Exclude coagulopathy or thrombocytopenia if indicated by history.</td>
<td>None required if no concerns for underlying ocular pathology and no acute complications.</td>
<td>Reassure patient that discoloration should resolve over 2 to 3 weeks.</td>
</tr>
<tr>
<td>6. Corneal perforation: Direct visualization of full-thickness injury or positive Seidel’s test</td>
<td>Protect eye from further pressure, provide pain relief, and prevent vomiting. Parenteral antibiotic and tetanus prophylaxis.</td>
<td>Ophthalmologist must come to ED to evaluate.</td>
<td>Admit for continuation of antibiotics and procedural intervention.</td>

<td>7. Ruptured globe: Misshaped cornea or globe following trauma</td>
<td>Protect eye from further pressure, provide pain relief, and prevent vomiting. Parenteral antibiotic and tetanus prophylaxis.</td>
<td>Ophthalmologist must come to ED to evaluate.</td>
<td>Admit for continuation of antibiotics and procedural intervention.</td>
</tr>
<tr>
<td>8. Corneal abrasion: History of direct trauma or foreign body plus direct visualization of defect in the corneal epithelium using white light, or fluorescein and blue light; any surrounding corneal edema indicates a concomitant keratitis (see #19)</td>
<td>Antibiotic prophylaxis with polymyxin-B/thrombopirin solution 1 drop every 3 hours while awake and erythromycin ointment while sleeping.</td>
<td>Discuss plan for follow-up in 1 to 3 days.</td>
<td>May discharge if no other findings. No patch.</td>
</tr>
<tr>
<td>9. Traumatic mydriasis: Nonreactive dilated pupil without any other identifiable eye abnormalities following blunt trauma</td>
<td>None once other abnormalities of the eye, cranial nerves, and brain have been reasonably excluded.</td>
<td>Discuss plan for follow-up evaluation of slowly developing hyphema and ensure resolution.</td>
<td>May discharge if no other findings.</td>
</tr>
<tr>
<td>10. Inflammatory pseudotumor: Nonspecific idiopathic retrobulbar inflammation with eyelid swelling, palpebral injection of conjunctiva, chemosis, proptosis, blurred vision, painful or limited ocular mobility, binocular diplopia, edema of optic disk, or venous engorgement of retina</td>
<td>Measure IOP and rule out orbital compartment syndrome. Start parenteral antibiotics with second-generation cephalosporin (eg, cefuroxime, cefotixin, or cefotetan) or with ampicillin/sulbactam to cover sinus and skin flora. Alternatives are ticarcillin/clavulanate, piperacillin/tazobactam, vancomycin, or clindamycin + third-generation cephalosporin (eg, cefotaxime or ceftriaxone).</td>
<td>IOP &gt;20 mm Hg may be surgical emergency, may add medications used in glaucoma #18 to decrease IOP before decompression in ED.</td>
<td>May discharge if no systemic problems, no findings of particular concern on CT, and IOP ≤20 mm Hg. Start high-dose PO antibiotics after discussion with ophthalmologist, and ensure reevaluation in 2 to 3 days.</td>
</tr>
<tr>
<td>11. Orbital cellulitis: Eyelid swelling, redness and warmth of skin overlying orbit, tenderness of skin overlying bone palpebral injection of conjunctiva, and chemosis; differentiated from periorbital cellulitis by presence of any finding of fever, ill appearance, blurred vision, proptosis, painful or limited ocular mobility, binocular diplopia, edema of optic disk, or venous engorgement of retina</td>
<td>First rule out orbital cellulitis (see #11). PO antibiotics for sinus and skin flora if not admitting.</td>
<td>Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient.</td>
<td>May discharge mild cases with PO antibiotics. Ophthalmologist must reevaluate next day to ensure no orbital extension.</td>
</tr>
<tr>
<td>12. Periorbital cellulitis or erysipelas: Eyelid swelling, redness and warmth of skin overlying orbit, tenderness of skin overlying bone, palpebral injection of conjunctiva, and chemosis; differentiated from orbital cellulitis by absence of any other finding listed in #11</td>
<td>First rule out orbital cellulitis (see #11). PO antibiotics for sinus and skin flora if not admitting.</td>
<td>Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient.</td>
<td>May discharge mild cases with PO antibiotics. Ophthalmologist must reevaluate next day to ensure no orbital extension.</td>
</tr>
<tr>
<td>13. Dacryocystitis and dacryadenitis: Eye tearing and inflammation of lower eyelid inferior to lacrimal punctum finding redness and tenderness over nasal aspect of lower lid and adjacent periorbital skin</td>
<td>First rule out orbital cellulitis (see #11) and periorbital cellulitis (see #12). Inspect for obstruction of punctum by SLE, may express pus by pressing on sac, PO antibiotics for nasal and skin flora if not admitting.</td>
<td>Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient. Ask about culturing before prescribing medications if admitting, and then may add medications used in glaucoma #18 to decrease IOP before decompression.</td>
<td>May discharge mild cases with PO analgesics and antibiotics (eg, amoxicillin/clavulanate), and instructions to apply warm compresses to eyelids for 15 minutes and gently massage inner canthal area four times a day.</td>
</tr>
<tr>
<td>14. Orbital tumor: Blurred vision, proptosis or other displacement of globe, painful or limited ocular mobility, or binocular diplopia (but can be asymptomatic)</td>
<td>Measure IOP. Evaluate for extraocular signs of malignancy. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.</td>
<td>IOP &gt;20 mm Hg may be surgical emergency, prescribe to decrease IOP in ED. Ophthalmologist may want MRI, MRA, or orbital ultrasonography.</td>
<td>Based on findings and discussion with consultant.</td>
</tr>

</tr>
<tr>
<td><strong>19. Keratitis (abrasion or UV injury): Pain, FB sensation, blepharospasm, tearing, photophobia, epithelial disruption on inspection under white light, or fluorescein pooling under blue light; SPK appears as stippling of corneal surface (often lower two thirds of cornea if due to light exposure); if neglected for a time, may have surrounding edema appearing as white “cloudiness” in clear tissue.</strong></td>
<td>First rule out corneal penetration either grossly or employing Seidel’s test. Relieve pain and blepharospasm with topical anesthetic. Inspect all conjunctival recesses and superficial cornea for any foreign material that can be removed by irrigation or manually lifted from surface. Ophthalmologist must come to ED if there is any concern for globe penetration. Otherwise consult for follow-up examination in 1 to 2 days. May discharge cases not infected or ulcerated. May provide topical antibiotic prophylaxis using polymyxin B combinations with bacitracin (ointment) or trimethoprim (solution). Erythromycin, gentamicin, and sulfacetamide are less desirable single-agent alternatives. PO NSAIDs or narcotics for analgesia. No patch.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

*TABLE 19.1 Management Algorithm for Red Eyes Extended from Diagnostic Algorithm in Figure 19.8*
### POTENTIAL DIAGNOSIS

**Keratitis (ulceration):** Symptoms and signs as described above; ulceration from complications of contact wear has “scooped out” epithelium with surrounding edema appearing as white “cloudiness” in clear tissue

**Keratitis (herpetic infection):** Symptoms and signs as described above  
Look for other signs of herpes, varicella, zoster (or CMV infection in immunocompromised patient)  
Look for “dendritic” defects of cornea with fluorescein under blue light

---

### MANAGEMENT

**Keratitis (ulceration):**  
Relieve pain and blepharospasm with topical anesthetic. *Staphylococcus* and *Streptococcus* species still most common organisms, but *Pseudomonas* greater percentage in existing infections (especially contact lens wearer), so prescription with topical fluoroquinolone is preferred.

**Keratitis (herpetic infection):**  
Relieve pain and blepharospasm with topical anesthetic. Prescribe acyclovir 3% ointment, trifluridine 1% solution, or vidarabine ointment. Varicella-zoster and CMV not normally given antivirals if immunocompetent.

---

### CONSULTATION

**Keratitis (ulceration):** Discuss with ophthalmologist any potential need to débride or culture before starting antibiotic.

**Keratitis (herpetic infection):** Discuss with ophthalmologist any potential need to débride or culture before starting antiviral.

---

### DISPOSITION

**Keratitis (ulceration):** Based on findings and discussion with consultant. Typical ciprofloxacin dosing is 2 drops q15min for 6 hours, then 2 drops q30min day and night for remainder of day 1 until seen by consultant the next day. Typical moxifloxacin dosing is 1 drop q15min for 1 hr, then 1 drop q1hr day and night until seen by consultant the next day. For large ulcerations or ulcers near the visual axis, a fortified antibiotic, such as tobramycin, may be added.

**Keratitis (herpetic infection):** Based on findings and discussion with consultant. Typical vidarabine or acyclovir dosing is five times a day for 7 days, then taper over 2 more weeks. Typical trifluridine dosing is 1 drop every 2 hours for 7 days, then taper over 2 more weeks. PO NSAIDs or narcotics for analgesia. No patch.

---

### 20. Scleritis: Progressively increasing eye pain with radiation to ipsilateral face and decreasing vision, photophobia, tearing, and possible pain with eye motion

Decrease inflammation with PO NSAIDs.

Discuss findings and use of topical or PO steroids.

May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2 to 3 days.

### 21. Anterior uveitis and hypopyon: Eye pain, photophobia, tearing, limbal injection of conjunctiva, and cells or flare in anterior chamber; hypopyon is layering of white cells (pus) in anterior chamber

First rule out glaucoma with IOP measurement. Prescribe in ED if IOP >20 mm Hg. Otherwise okay to dilate pupil with 2 drops of cyclopentolate 1%.

Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist but range is every 1 to 6 hours).

May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2 to 3 days. Patients with hypopyon are generally admitted.

### 22. Endophthalmitis: Progressively increasing eye pain and decreasing vision, diminished red reflex, cells and flare (and possibly hypopyon) in anterior chamber, chemosis, and eyelid swelling

Empirical parenteral antibiotic administration with vancomycin and ceftazidime to cover *Bacillus, enterococcus, and Staphylococcus spp*. Ciprofloxacin or levofloxacin are used when others contraindicated.

Ophthalmologist must admit for parenteral and possibly intravitreal antibiotics.

Admit all cases of endophthalmitis.

### 23. Keratoconjunctivitis: Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported

Treat for conjunctivitis by likely etiologic category (see #25 to #30).

Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2 to 3 days.

### 24. Episcleritis: Rapid onset of localized pain, injection of episcleral vessels, and localized tenderness

Relieve irritation with artificial tears and decrease inflammation with ketorolac drops.

Outpatient referral only for treatment failure after 2 weeks.

May discharge patient with PO NSAIDs alone or in combination with topical ketorolac drops.

### 25. Inflamed pinguecula: Inflammation of soft yellow patches in temporal and nasal edges of limbal margin

Decrease inflammation with naphazoline or ketorolac drops.

Outpatient referral only for treatment failure after 2 weeks.

Discharge to follow-up with ophthalmologist for possible steroid therapy or surgical removal.

### 26. Inflamed pterygium: Inflammation of firmer white nodules extending from limbal conjunctiva onto cornea

Decrease inflammation with PO NSAIDs.

Discuss findings and use of topical or PO steroids.

May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2 to 3 days.

---

**TABLE 19.1**

Management Algorithm for Red Eyes Extended from Diagnostic Algorithm in Figure 19.8*—cont’d
common practice despite an absence of supporting evidence. There is also no evidence supporting the practice of administering tetanus immunization to patients with superficial corneal abrasions, other than as a general public health measure. On the other hand, true open wounds of the adnexa or globe do require tetanus prophylaxis if the patient’s immunization status is not up to date.

Mydriatic and cycloplegic agents are also commonly prescribed but rarely are indicated. Their use is discussed in Chapter 61. Mydriatic agents are contraindicated in patients with narrow-angle glaucoma. Larger corneal lesions sometimes require a cycloplegic agent for pain relief, but this should be prescribed only for the few patients experiencing refractory iris spasm and not prophylactically.1

Treatment of bacterial keratitis and endophthalmitis is described in Chapter 61.

Most ED patients with eye complaints are candidates for discharge and, if indicated, follow-up in the ED or with an ophthalmologist in 1 to 2 days. Others may require referral only if there is lack of resolution or treatment fails. A few patients require admission for procedural intervention, parenteral antibiotic regimens, management of intractable pain, or further diagnostic evaluation. General consultation and disposition considerations for the most important entities are outlined in Table 19.1.

**KEY CONCEPTS**

- Critical diagnoses, such as caustic injury, orbital compartment syndrome, and acute angle closure glaucoma, require immediate treatment and ophthalmology consultation.
- Prompt and prolonged irrigation is advised for patients who experience caustic injury to the eye.
- Headache and nausea may be prominent symptoms in patients with acute angle-closure glaucoma.
- Complete abolition of a foreign body sensation after instillation of local anesthesia solution indicates a high likelihood of a superficial corneal lesion.
- Keratitis, inflammation of the cornea, is most commonly caused by a viral infection, but may also be caused by recent ultraviolet light exposure, chemical injury, or hypoxic injury from contact lens use.
- A localized corneal defect with edematous, inflammatory changes may signal corneal ulceration.
- A corneal dendritic pattern may signal a herpetic infection, which can progress to corneal opacification and visual loss.
- Pain, consensual photophobia, peri-limbic conjunctival infection, and a miotic pupil that is caused by ciliary spasm could signal iritis, which is inflammation of the iris and ciliary body, or uveitis, inflammation of the iris, ciliary body, and also choroids. The cause may be trauma or underlying autoimmune disease. The presence of cells and flare in the anterior chamber can help identify these conditions.
- Conjunctivitis is usually self-limited and rarely requires antibiotic treatment.

CHAPTER 19: QUESTIONS & ANSWERS

19.1. Cupping of the optic disk is most commonly seen in which of the following?
A. Glaucoma
B. Graves’ disease
C. Pseudotumor
D. Retinal detachment
E. Retrobulbar hematoma

Answer: A. Cupping of the optic disk results from increased intraocular pressure (IOP) and is seen quite frequently in patients with glaucoma, especially those with long-standing, uncontrolled disease.

19.2. A patient who normally wears contact lenses is diagnosed with bacterial conjunctivitis. Which of the following is the preferred treatment in this patient?
A. Bacitracin
B. Chloramphenicol
C. Erythromycin
D. Moxifloxacin
E. Sodium sulfacetamide

Answer: D. Patients who wear contact lenses are at increased risk for infections with *Pseudomonas* and, in the setting of bacterial conjunctivitis, should be prescribed a quinolone (eg, ciprofloxacin or moxifloxacin) barring any contraindications.

19.3. Which of the following provides the longest maximum duration of cycloplegia?
A. Atropine
B. Cyclopentolate
C. Homatropine
D. Scopolamine
E. Tropicamide

Answer: A. Atropine has a maximum duration of action of 14 days. This is followed by scopolamine with a maximum duration of 7 days, homatropine with 3 days, cyclopentolate with 24 hours, and tropicamide with 6 hours.

19.4. A 15-year-old boy presents to the ED after having been shot in the face with a BB gun. He has a solitary penetrating wound just inferior to his left eye. His visual acuity in the left eye is limited to light perception, but he reports having normal vision prior to the injury. He has significant proptosis of his left eye, and his fundus is clearly seen with direct ophthalmoscopy. Intraocular pressure (IOP) of the affected eye is 50 mm Hg. His mental status is normal. What is the most appropriate next step in the management of this patient?
A. CT scan of the head and face
B. ED observation with repeated neurologic examinations
C. Central retinal artery occlusion
D. Next-day referral to ophthalmology
E. Plain radiography of the face

Answer: B. Acute central retinal artery occlusion is characterized by a diffusely pale retina with indistinct vessels and a cherry-red fovea centralis. Her left eye is normal. Which of the following is the most likely diagnosis?
A. Acute angle closure glaucoma
B. Central retinal artery occlusion
C. Retinal detachment
D. Tay-Sachs disease
E. Temporal arteritis

Answer: C. Retinal detachment reveals a translucent retina that has lifted away from the underlying pigment epithelium. Finally, although patients with Tay-Sachs disease do have a cherry-red fovea, the remainder of the retina is not diffusely pale with poorly visualized vessels. Moreover, Tay-Sachs disease is manifested in the early part of life and would not first be coming to clinical attention in a 68-year-old patient.

19.5. A 68-year-old woman presents with a sudden, painless, and complete vision loss in her right eye. Upon funduscopic examination of her right eye, she is noted to have a diffusely pale retina with indistinct vessels and a cherry-red fovea centralis. Her left eye is normal. Which of the following is the most likely diagnosis?
A. Acute angle closure glaucoma
B. Central retinal artery occlusion
C. Retinal detachment
D. Tay-Sachs disease
E. Temporal arteritis

Answer: E. Temporal arteritis to further delineate specific injuries, lateral canthotomy and cantholysis is emergently necessary for orbital decompression in an attempt to salvage visual function. This sight-saving procedure should not be delayed more than 2 hours after injury when severe findings (decreased visual acuity and significantly increased IOP) are present. Likewise, ophthalmology consultation would be indicated emergently. Plain films of the face would prove of little use in the evaluation of this patient, as would prolonged ED observation.

19.6. A professional boxer presents to the ED after having been punched in the right eye during a boxing match 1 hour ago. He complains of decreased vision in the affected eye and is noted to have significant periorbital swelling and
proptosis. Intraocular pressure (IOP) is 35 mm Hg in his right eye. Which of the following is the most likely diagnosis?

A. Orbital cellulitis
B. Orbital compartment syndrome
C. Periorbital cellulitis
D. Post-traumatic glaucoma
E. Traumatic iritis

**Answer:** B. The most important cause of post-traumatic proptosis in the ED is the development of retrobulbar hematoma. This is characterized by hemorrhage within the bony orbit and behind the globe. With significant bleeding, an orbital compartment syndrome can occur in which the globe is pushed forward, the optic nerve and retinal artery are stretched and compressed, and the IOP is increased. This is a potentially sight-threatening condition that requires expeditious diagnosis and management if the vision is to be salvaged.

19.7. A collection of pus in the anterior chamber of the eye is known as which of the following?

A. Cotton-wool spot
B. Dacryocystitis
C. Hyphema
D. Hypopyon
E. Keratitis

**Answer:** D. A collection of layered pus in the dependent portion of the anterior chamber is called a hypopyon.

19.8. Which of the following results from inflammation of a meibomian gland?

A. Blepharitis
B. Chalazion
C. Dacryocystitis
D. Erysipelas
E. Hordeolum

**Answer:** B. Inflammation of a meibomian gland with the subsequent formation of a subcutaneous nodule within the eyelid is known as a chalazion. This condition typically resolves spontaneously over several days. Authorities often recommend warm compress application and gentle massage of the nodule several times a day, although there is no evidence supporting this. If complete resolution does not occur within 2 weeks, the patient should be referred to an ophthalmologist.

19.9. Which of the following pathogens causes a characteristic dendritic lesion on the cornea?

A. *Chlamydia trachomatis*
B. Coxsackievirus
C. Herpes simplex virus
D. *Neisseria gonorrhoeae*
E. *Pseudomonas aeruginosa*

**Answer:** C. Herpes simplex virus causes a characteristic corneal dendritic lesion that is readily seen during slit-lamp examination under blue light as fluorescein stain pools in the defect. The importance of recognizing this lesion and diagnosing HSV infection of the eye is tremendous, because infections of the cornea with HSV can rapidly lead to corneal opacification and permanent loss of vision.
Sore Throat

Amy H. Kaji

CHAPTER 20

Sore Throat

Epidemiology

Sore throat and throat-related complaints are among the most common presenting complaints, not just in emergency departments (EDs) but also in outpatient care settings in the United States. Although individuals of all ages commonly develop sore throat, some subtypes of pharyngitis and peripharyngeal disorders are more common in children and adolescents. For example, the epidemiology of group A streptococcal pharyngitis is characteristic in that it is primarily a disease of children 5 to 15 years of age and is rarely seen in those younger than 3 years.

Pathophysiology

Sore throat, or pharyngitis, is generally caused by inflammation in the soft tissue of the pharynx. There are three anatomically distinct regions of the pharynx—the nasopharynx, oropharynx, and hypopharynx (Fig. 20.1). Pathology involving one site usually involves the others, but inflammation at any of these levels can manifest as a sore throat. The nasopharynx encompasses the area superior to the oral cavity, between the base of the skull and soft palate. The eustachian tubes, connecting the middle ear and pharynx, open into this space. The oropharynx is the region directly visible on examination, lying behind the oral cavity, between the uvula and hyoid, including the vallecula and epiglottis. Laterally, it is defined by the tonsillar pillars. The hypopharynx is the most caudal aspect of the pharynx. It lies inferior to the epiglottis and terminates where the aerodigestive paths become distinct, at the esophagus and larynx; the vocal cords define the inferior pole. If one looks directly at a patient, this region is posterior and slightly superior to the thyroid cartilage. There are several important potential spaces surrounding the pharynx; disease in the retropharyngeal and submandibular spaces can manifest as pain and, ultimately, airway compromise.

The terms pharyngitis and tonsillitis are often used interchangeably; however, the tonsils are distinct lymph tissue located throughout the pharynx. Waldeyer’s tonsillar ring, or the pharyngeal lymphoid ring, consists of the pharyngeal (adenoids), tubal, palatine, and lingual tonsils. The palatine tonsils are located on the sides of the oropharynx, between the palatoglossal and palatopharyngeal arches. These immunologic masses are commonly implicated in sore throat and are referred to colloquially as the tonsils. Regional infections, viral and bacterial, commonly trigger inflammatory changes in this collection of lymphatic tissue. Whereas inflammation and swelling of the soft tissues in the oropharynx are the most likely cause in patients with a sore throat, any of the anatomic structures or surfaces within the nasopharynx or hypopharynx can be affected by disease leading to a sore throat. Cranial nerves IX and X supply sensory innervation to the region.

PERSPECTIVE

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis for sore throat presentations is extremely broad, but major categories to consider in order of frequency include infectious and noninfectious (neoplastic, inflammatory, traumatic) and referred pain from acute coronary syndrome.

Pivotal Findings

Symptoms and Signs

The evaluation of sore throat begins with a simultaneous assessment of the airway and the patient’s general appearance. The general appearance should be assessed, with attention to hydration status and markers of systemic toxicity. Patients, particularly children, with significant pain from uncomplicated pharyngitis often have difficulty with oral intake and may become dehydrated. Fever and mild tachycardia are common vital sign derangements often have difficulty with oral intake and may become dehydrated. Fever and mild tachycardia are common vital sign derangements. Patients with airway compromise often sit upright or lean forward, with the neck extended and jaw thrust forward, and appear restless and distressed. Drooling may indicate an inability to swallow oral secretions and thus inflammation or pathology in the oropharynx or hypopharynx may be present. Drooling is a sign of an advanced airway process, requiring prompt preparation for detailed evaluation and intervention. The presence of a muffled voice should prompt consideration of a supraglottic threat to airway patency. The floor of the mouth should be visualized and, when indicated, the submental region palpated as a brawny induration or tenderness in this area is classically associated with Ludwig’s angina (Table 20.1). Stridor, a high-pitched noise heard on inspiration, suggests a process involving the glottic or infra-glottic structures. Stridor indicates partial obstruction, a true airway emergency except when occurring in young children (<10 years) with croup (see Chapter 167). Stridor is associated with ominous conditions such as epiglottitis, retropharyngeal abscess, and angioedema, and the severity, rate of onset, and progression of symptoms may help indicate the urgency of any required intervention. Patients who have a mass lesion causing sore throat symptoms may have associated dysphagia or odynophagia, hoarseness, weight loss, and lymphadenopathy. Those who have acute coronary syndrome with referred throat pain may have associated chest pain, dyspnea, or diaphoresis.

Direct visualization of the pharynx is typically the most helpful portion of the encounter; thus, complete and unencumbered visualization of the pharyngeal structures is mandatory. Lingual resistance may require coaching or stimulation of a gag reflex, and trismus or pain will often require analgesia. If impressive tonsillar

Fig. 20.1. Anatomy of the nasopharynx, oropharynx, and hypopharynx.

Erythema or exudates are observed in a symmetric distribution, and the patient has no signs of airway involvement, acute tonsillitis is present, and further investigation is rarely warranted. There are various scoring systems, the most well-known of which is the Centor criteria system (Table 20.2), which incorporate components of the history and physical examination to generate an estimate of the likelihood of group A streptococcal infection (GAS). The four Centor criteria are history of fever, tonsillar exudates, tender anterior cervical adenopathy, and absence of cough. A later modification added a fifth criterion (subtract 1
point for age >45 years). Using the criteria, the prevalence of GAS is about 50% in patients with scores of 4 or higher, one third with a score of 3, less than 20% with a score of 2, 10% with a score of 1, and near zero with a score of 0 or –1. In contrast, visualization of ulcerations, or presence of rhinorrhea, sneezing, or conjunctivitis point more to a viral cause of the pharyngitis. Unilateral swelling and contralateral uvular deviation, typically without exudates, suggest peritonsillar abscess. Involvement of the entire oropharynx indicates pharyngitis. If, however, the patient has significant symptoms and no oropharyngeal pathology on examination, evaluation for disease in the hypopharynx, especially epiglottitis, by direct or indirect visualization is indicated. Other potential sinister causes for when a patient presents with significant symptoms and a relatively normal oropharyngeal examination include retropharyngeal abscess and parapharyngeal abscess.

Ancillary Testing

In the context of acute pharyngitis, diagnostic testing with the rapid antigen detection test (RADT) or culture is helpful to distinguish between GAS and non-GAS pharyngitis (particularly viral causes) for the purpose of selecting patients who may benefit from antimicrobial therapy. If the patient has a clear-cut viral cause for the pharyngitis, with oral ulcers, cough, rhinorrhea, and hoarseness, then no testing (or treatment) for GAS is indicated. Additionally, because of the rarity of GAS and rheumatic fever in children younger than 3 years, testing is also generally not indicated in this age group. Unfortunately, even with the use of the Centor criteria, clinical features alone often do not allow the emergency clinician to discriminate GAS from viral pharyngitis reliably, and the overprescribing of inappropriate antimicrobial therapy for viral pharyngitis contributes to the undesirable adverse effects of (unnecessary) antibiotics and to antimicrobial resistance. The primary reasons for treating patients with culture-proven GAS in the setting of acute pharyngitis are to decrease the risk of supplicative (eg, peritonsillar abscess, cervical lymphadenitis, mastoiditis, possibly internal jugular septic thrombophlebitis) and nonsupplicative (acute rheumatic fever) complications of GAS. Additionally, antimicrobial treatment may decrease the duration and severity of illness and reduce the risk of transmission to close contacts. Although many western industrialized nations, where rheumatic fever tends to be exceedingly rare, have abandoned this approach because the inaccuracy and risks of testing and treatment seem to outweigh benefits, the Centers for Disease Control and Prevention (CDC) and Infectious Disease Society of America (IDSA) guidelines of 2012 recommend a combination of clinical assessment and bacteriologic testing, with the goal of treating with antibiotics for proven or strongly suspected GAS. Because the sensitivity of the RADT is only approximately 70% to 90%, the IDSA recommends that for children and adolescents, a negative RADT should be followed up with a throat culture. In contrast, a positive RADT does not warrant follow-up throat culture testing because of its high specificity (95%). The IDSA does not recommend that a negative RADT be followed up with a throat culture in adults, in whom the incidence of GAS and risk of subsequent rheumatic fever is extremely low, when compared to children and adolescents.

Heterophile antibody testing for mononucleosis, testing for acute retroviral syndrome, and other possibilities may also be considered in patients with an extended clinical course, unusual features, or treatment failure, largely to exclude other causes and to ensure appropriate advice regarding issues such as contagion and activity limitations (see Chapters 82 and 122).

Imaging

Although radiographic imaging has long been recommended for evaluation of the epiglottis and structures in the hypopharynx, direct visualization of the structures of interest by examination is preferable, providing definitive diagnosis, assessment of airway threats, and the ability to plan for or perform endotracheal intubation. In adults with possible epiglottitis, particularly those with severe symptoms such as drooling, distress, or muffled voice, examination via nasopharyngoscopy at the bedside or via laryngoscopy in the operating room setting is the best approach. Examination of this sort, however, should occur under a so-called double setup, with availability of and preparation for an emergent rescue airway, usually cricothyrotomy, because manipulation of the irritated upper airway tissues may precipitate laryngospasm and obstruction. Endoscopic examination also allows identification of other life-threatening causes beyond infection such as foreign bodies, polyps, and angioedema. If there is concern for epiglottitis but upper airway examination by endoscopy is not possible (eg, equipment unavailable) and the patient has a stable airway, plain film radiography may be useful to assess for changes such as the thumb sign—widening of the epiglottis silhouette (Fig. 20.2). The approach to pediatric airway infection, including epiglottitis, is described in Chapters 167 and 168.

Ultrasound is another technology with applications for the detection of neck masses from tumors and hypopharyngeal conditions, including epiglottitis. In a convenience sample of adults, the epiglottis was easily visualized and measured in males and females, and recent case reports, as well as a small, controlled ED study of ultrasound for epiglottitis, have suggested that this noninvasive bedside tool may prove useful.

In a child or adult with signs and symptoms of a deep neck infection such as retropharyngeal abscess and whose airway security has been ensured, the most useful imaging modality is computed tomography (CT) of the neck. The lateral neck x-ray examination is a relatively sensitive test for this disease, so in lower risk patients a normal film (no widening of the prevertebral space, normal lordotic curve of the spine, and absence of soft tissue air)

GABHS, group A beta-hemolytic streptococci; LAD, lymphadenopathy.
examination, ideally while initiating any available consultations such as otolaryngology or surgical services. This examination should concentrate on the detection of masses such as sublingual edema, visible abscess, and foreign bodies. If such a mass can be visualized, disease-specific decisions about imaging, potential airway management, or surgical procedures (eg, abscess drainage) can be made.

In patients without signs of airway compromise, the pace of execution can be more deliberate; a primary question is whether or not findings consistent with pharyngitis are visible. If exudates, erythema, or cobblestoning of the posterior pharyngeal wall is evident, pharyngitis is likely present. At this point, consideration of less common causes (eg, gonococcal infection, mononucleosis) should be explored by concentrating on features in the history such as recent exposures and duration, and the possibility of extremely rare entities (eg, Lemierre’s syndrome) may be entertained as well. In the absence of unusual features that predispose to these diagnostic possibilities, pharyngitis is likely to be viral or streptococcal in origin and may be empirically managed as such.

**DIAGNOSTIC ALGORITHM**

**Critical and Emergent Diagnoses**

Box 20.1 outlines critical diagnoses and emergent diagnoses that have the potential to cause airway compromise that may warrant specific intervention. For example, in patients with Ludwig’s angina, securing the airway, promptly initiating antibiotic treatment and fluid resuscitation, and obtaining prompt evaluation by an otolaryngologist may be lifesaving. If there are signs of airway compromise or impending airway compromise in addition to preparing for advanced airway management, the emergency clinician should immediately move to a detailed intraoral physical examination, ideally while initiating any available consultations such as otolaryngology or surgical services. This examination should concentrate on the detection of masses such as sublingual edema, visible abscess, and foreign bodies. If such a mass can be visualized, disease-specific decisions about imaging, potential airway management, or surgical procedures (eg, abscess drainage) can be made.

In patients without signs of airway compromise, the pace of execution can be more deliberate; a primary question is whether or not findings consistent with pharyngitis are visible. If exudates, erythema, or cobblestoning of the posterior pharyngeal wall is evident, pharyngitis is likely present. At this point, consideration of less common causes (eg, gonococcal infection, mononucleosis) should be explored by concentrating on features in the history such as recent exposures and duration, and the possibility of extremely rare entities (eg, Lemierre’s syndrome) may be entertained as well. In the absence of unusual features that predispose to these diagnostic possibilities, pharyngitis is likely to be viral or streptococcal in origin and may be empirically managed as such.

**EMPIRICAL MANAGEMENT**

Fig. 20.4 shows a clinical algorithm for the initial management of the sore throat presentation. Airway compromise and impending airway compromise, when present, must be addressed first. Infectious syndromes suggesting severe systemic illness or sepsis should be treated accordingly. Patients who clinically appear to have no potential for airway compromise and no signs of invasive or systemic disease can be managed according to presumptive causes.

Usually, sore throat will be caused by viral pharyngitis, in which case pain management with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) is the mainstay of care and the most important initial step in empirical management. Regimented administration of these agents, rather than the use of as-needed approaches that fail to prevent or interrupt spiraling pain, is often helpful. Two recent systematic reviews have concluded that acute pharyngitis, including GAS pharyngitis, should not routinely be treated with antibiotics. It is thought that the decline of rheumatic fever may be unrelated to trends in antibiotic
Thus, for public health reasons and prevention of unnecessary individual harm, antibiotics should be avoided in the management of viral pharyngitis. Education of patients, who will often expect or desire antibiotics, is a key part of management. Education should provide a careful explanation of the following: (1) the self-limited nature of viral pharyngitis; (2) the lack of symptomatic or other benefit with antibiotics; and (3) the potential harm of antibiotics (eg, individual and population resistance, fungal infections in women, rashes, gastrointestinal effects, recurrence of pharyngitis, occasionally dangerous allergic reactions). It is often most important to emphasize that symptom reduction can be achieved with the use, but rather is a result of factors associated with industrialization, including improved living conditions, access to care, hygiene, and nutrition. This explains the current epidemiology of rheumatic fever, a disease that is extremely rare in developed nations but continues to be an important public health threat in developing regions worldwide. Notably, adverse events caused by antibiotics are common and frequently result in ED visits, and the overuse of antibiotics for self-limiting conditions such as upper respiratory tract infections remains rampant. Indeed, the inappropriate prescription of antibiotics for viral pharyngitis in the United States has remained unchanged over time in recent decades, even despite extensive public health messaging to reduce the problem. Thus, for public health reasons and prevention of unnecessary individual harm, antibiotics should be avoided in the management of viral pharyngitis.

This explains the current epidemiology of rheumatic fever, a disease that is extremely rare in developed nations but continues to be an important public health threat in developing regions worldwide. Notably, adverse events caused by antibiotics are common and frequently result in ED visits, and the overuse of antibiotics for self-limiting conditions such as upper respiratory tract infections remains rampant. Indeed, the inappropriate prescription of antibiotics for viral pharyngitis in the United States has remained unchanged over time in recent decades, even despite extensive public health messaging to reduce the problem. Thus, for public health reasons and prevention of unnecessary individual harm, antibiotics should be avoided in the management of viral pharyngitis.

Education of patients, who will often expect or desire antibiotics, is a key part of management. Education should provide a careful explanation of the following: (1) the self-limited nature of viral pharyngitis; (2) the lack of symptomatic or other benefit with antibiotics; and (3) the potential harm of antibiotics (eg, individual and population resistance, fungal infections in women, rashes, gastrointestinal effects, recurrence of pharyngitis, occasionally dangerous allergic reactions). It is often most important to emphasize that symptom reduction can be achieved with the use, but rather is a result of factors associated with industrialization, including improved living conditions, access to care, hygiene, and nutrition. This explains the current epidemiology of rheumatic fever, a disease that is extremely rare in developed nations but continues to be an important public health threat in developing regions worldwide. The presence of such severe pain may indicate a more severe syndrome such as abscess or epiglottitis, requiring additional evaluation. Proper pain management allows patients to reestablish nutritional balance, achieve and maintain a hydrated state, and ingest medications, as necessary.

In the setting of clinical pharyngitis, a fluctuant unilateral peritonsillar mass should be drained whenever possible. Drainage in such cases constitutes definitive care. Although there are no data to support or refute the administration of antibiotics in cases of unilateral swelling and redness that appears not to be fluctuant (ie, so-called peritonsillar cellulitis), I recommend the same antibiotics that are used for GAS pharyngitis for these patients (see Box 20.2). For patients with manifestations of severe, systemic illness (ie, those requiring hospitalization or with impending airway compromise), antibiotic coverage for streptococcal and anaerobic bacteria may theoretically be helpful. I recommend the administration of parenteral clindamycin (900 mg tid) and a third-generation cephalosporin such as ceftriaxone (50 mg/kg or 1 g bid), although no firm evidence is available to support or refute this practice. Other specific empirical therapies or consultation may be necessary for severe or unusual presentations of disease.

Finally, the great majority of patients will be able to manage their condition on an outpatient basis. For those with actively present or potentially impending airway threat, surgical intensive care settings are often appropriate, although this will depend on nursing ratios, local comfort level with airway management, and ability for the patient to be monitored closely in alternate settings. In such cases, as well as in cases of confirmed deep space infection (eg, neck abscess, parapharyngeal abscess, Ludwig’s angina), surgical consultation for potential operative management or for imaging modalities such as nasopharyngoscopy is generally important and helpful. Some patients with pharyngitis may also benefit from inpatient management, usually those with systemic illness who are unable to tolerate oral therapies or nutrition.

Various interventions that target pain control—for example, NSAIDs.

However, major organizations such as the IDSA and CDC support targeted testing and antimicrobial therapy for proven GAS pharyngitis and tonsillitis. Moreover, because eradicating GAS from the pharynx with appropriate antibiotic administration may reduce the duration and severity of illness, decrease the risk for suppurative and nonsuppurative complications, and reduce infectivity and transmission to close contacts, I recommend treatment with intramuscular benzathine penicillin G or a 10-day course of oral penicillin VK because of proven efficacy and low cost. See Box 20.2 for antibiotic regimens and alternative agents for those who are allergic to penicillin. For severe pharyngitis causing difficulty swallowing, corticosteroid therapy reduces pain and duration of pain, with most studies using 0.6 mg/kg (maximum dose, 10 mg) of dexamethasone, orally or parenterally, in a single dose. Opioid pain medication rarely is indicated, and the presence of such severe pain may indicate a more severe pharyngitis, which is self-limiting.

**KEY CONCEPTS**

- Sore throat is a chief complaint that can represent life-threatening diagnoses and extreme challenges for the emergency clinician, primarily in the form of airway threats and/or deep space infections.
- The five modified Centor criteria award 1 point for each of the following: (1) history of fever; (2) presence of exudates; (3) presence of anterior cervical adenopathy; and (4) absence of cough, and subtract 1 point for (5) age older than 45 years. Patients with scores of −1 to 1 are very unlikely to have GAS infection. Scores of 4 or 5 correspond to a 50% likelihood of GAS, which drops to approximately 30% with a score of 3 and below 20% with a score of 2.
- Physical examination is central to detecting airway threats and determining diagnosis.
- The absence of physical findings during oropharyngeal examination in the setting of severe sore throat symptoms suggests that lower structures may be involved, and endoscopic examination of the upper airway is advisable.
- Antibiotics are more harmful than helpful for patients with viral pharyngitis, which is self-limiting.
- For GAS-proven pharyngitis, a single injection of penicillin or 10-day course of oral penicillin is recommended to decrease the duration of symptoms, transmission to close contacts, and prevention of the rare suppurative and nonsuppurative sequelae.

CHAPTER 20: QUESTIONS & ANSWERS

20.1. When a patient presents to the emergency department (ED) complaining of a sore throat, which is the most valuable component of the diagnostic evaluation? 
A. Computed tomography (CT) evaluation of the soft tissues  
B. Direct visualization of the oropharynx  
C. Plain film radiography  
D. Serologic testing  

Answer: B. Direct visualization of the oropharynx is typically the most helpful portion of the encounter. Thus, complete and unencumbered visualization of the pharyngeal structures is mandatory. Lingual resistance may require coaching or stimulation of a gag reflex, and trismus or pain will often require analgesia. If impres- 
ationate to the physical examination, is concerning for other more 

20.2. Historically, there was emphasis on determining whether infectious pharyngitis was bacterial or viral in origin. Many industrialized countries have abandoned the search for group A streptococcal in the context of pharyngitis for the following reason(s): 
A. All of these  
B. Antibiotics do not improve the symptoms associated with viral pharyngitis.  
C. Risks of treatment outweigh benefits.  
D. The prevalence of rheumatic fever is exceedingly rare in industrialized nations.  

Answer: A. The great majority of cases are viral in origin, and supplicative complications following streptococcal infection are easily treated and occur too rarely to justify routine use of antibi- 

otics. Rheumatic fever is a disease that is extremely rare in developed nations. Additionally, adverse events caused by antibi- 

otics are common and frequently result in ED visits.  

20.3. A 40-year-old man presents with a complaint of sore throat. He is febrile, 102°F (39°C), reports considerable pain with swallowing, and has a moderate sensation of tightness in his throat. On examination, you note that the patient is sitting up; you observe only mild erythema to the tonsillar tissue. What should be the next step? 
A. Discharging patient home with a prescription for nonsteroidal antiinflammatory drugs (NSAIDs)  
B. Intramuscular injection of penicillin  
C. Nasopharyngoscopy at the bedside  
D. Sending the patient to radiology for a CT scan of the neck  

Answer: C. The severity of his symptoms, which are disproportionately to the physical examination, is concerning for other more sinister diagnoses such as epiglottitis, parapharyngeal abscess, and retropharyngeal abscess.  

20.4. A healthy 20-year-old, nonsexually active female presents with a complaint of a sore throat. She is febrile and mildly tachycardic. On evaluation, she looks uncomfortable but is in no distress. She has cervical adenopathy, and direct visualization of the oropharynx reveals symmetric tonsillar erythema and diffuse exudates. Ideal management for this patient would include which of the following? 
A. Ceftriaxone, 250 mg IM once  
B. Ibuprofen, 400 mg every 4 to 6 hours, dexamethasone (Decadron), 10 mg once, and acetaminophen-oxycodone (Percocet), 5/325 mg qid PRN  
C. Ibuprofen 400 mg every 4 to 6 hours, penicillin G IM once  
D. Unasyn (Ampicillin-sulbactam), 3 g IV, and incision and drainage  

Answer: C. Usually, sore throat is caused by acute pharyngitis, in which case pain management with acetylsalicylic or NSAIDs is the mainstay of care and the most important initial step in empiri- 

cal management. The Centor criteria, incorporating components of the history and physical examination to generate an estimate of group A streptococci (GAS), are listed in Table 20.2 with the results of one classic study, and this patient would be a candidate for antibiotic treatment.
Hemoptysis

Calvin A. Brown III

PERSPECTIVE

Epidemiology

Hemoptysis is defined as the expectoration of blood from the respiratory tract below the vocal cords. Most cases seen in the emergency department (ED) are mild episodes of small-volume hemoptysis, typically consisting of either blood-tinged sputum or minute amounts of frank blood, most often associated with bronchitis. Although hemoptysis is commonly seen in the ED, only 1% to 5% of hemoptysis patients have massive or life-threatening hemorrhage. Many definitions exist, but massive hemoptysis is generally accepted as 100 to 600 mL of blood loss in any 24-hour period, which can result in hemodynamic instability, shock, or impaired alveolar gas exchange and has a mortality rate approaching 80%.

Large, contemporary series of patients with massive hemoptysis are lacking, and most causative data originate from small, often rural, studies in which tuberculosis (TB) and bronchiectasis are responsible for the majority of cases. In developed nations, cancer, cystic fibrosis, arteriovenous malformations, anticoagulant use, and postprocedural complications play more prominent roles. Pediatric hemoptysis is rare but can be caused by infection, congenital heart disease, cystic fibrosis, or bleeding from a preexisting tracheostomy. Major causes of hemoptysis are listed in Box 21.1.

Pathophysiology

Minor hemoptysis typically originates from tracheobronchial capillaries that are disrupted by vigorous coughing or minor bronchial infections. Conversely, massive hemoptysis nearly always involves disruption of bronchial or pulmonary arteries, which are the two sets of vessels that constitute the lung’s dual blood supply. Bronchial arteries, which are direct branches from the thoracic aorta, are responsible for supplying oxygenated blood to lung parenchyma, and disruption of these vessels from arteritis, trauma, bronchiectasis, or malignant erosion can result in sudden and profound hemorrhage. Although small in caliber, the bronchial circulation is a high-pressure system and the culprit in nearly 90% of the cases of massive hemoptysis requiring embolization. Pulmonary arteries, although transmitting large volumes of blood, do so at much lower pressures and, unless affected centrally, are less likely to cause massive hemoptysis.

Nearly all causes of hemoptysis have a common mechanism—vascular disruption within the trachea, bronchi, small-caliber airways, or lung parenchyma. Modes of vessel injury include acute and chronic inflammation (from bronchitis and arteritis), local infection (especially lung abscesses, TB, and aspergillosis), trauma, malignant invasion, infarction following a pulmonary embolus, and fistula formation (specifically aortobronchial fistulae).

In the 1960s, nearly all cases of massive hemoptysis were a result of TB, bronchiectasis, or lung abscess. Each of these has since decreased in frequency, whereas pneumonia and bleeding diathesis have become more prevalent.

Bronchiectasis, a chronic necrotizing infection resulting in bronchial wall inflammation and dilation, is one of the most common causes of massive hemoptysis worldwide. As tissue destruction and remodeling occur, rupture of nearby bronchial vessels can result in bleeding. Bronchiectasis can complicate chronic airway obstruction, necrotizing pneumonia, TB, or cystic fibrosis. Broncholithiasis, the formation of calcified endobronchial lesions following a wide array of granulomatous infections, is an uncommon problem with a similar propensity to erode nearby vessels. Hemorrhage control often requires surgical intervention.

Iatrogenic hemoptysis complicates 2% to 10% of all endobronchial procedures, especially percutaneous lung biopsies. Right (pulmonary artery) heart catheterization using a Swan Ganz catheter can cause iatrogenic pulmonary artery perforation especially in patients with pulmonary hypertension. Although this complication is rare, the mortality is between 50% to 70%. Diffuse alveolar hemorrhage can be seen with autoimmune vasculitides, such as Wegener’s granulomatosis, systemic lupus erythematosus (SLE), and Goodpasture’s syndrome. An uncommon cause of hemoptysis occurs when ectopic endometrial tissue within the lung results in monthly catamenial episodes of bleeding. Less common causes include pulmonary hereditary telangiectasias and hydatidiform infections. Any episode of hemoptysis can be exacerbated by coagulopathy and thrombocytopenia.

DIAGNOSTIC APPROACH

Differential Diagnosis Considerations

First, the clinician should be convinced that the source of the bleeding is pulmonary. Distinguishing hemoptysis from hematemesis is accomplished by the clinician working with the patient to clarify details of the history, particularly differentiation between coughing and vomiting or spitting. Nasal, oral, or hypopharyngeal bleeding may contaminate the tracheobronchial tree, mimicking true hemoptysis. The clinician should closely inspect the nasopharynx and oral cavity to exclude this possibility. Gastric or proximal duodenal bleeding can similarly mimic hemoptysis, and differentiating a gastrointestinal (GI) source of bleeding is especially important because further evaluation and management of these two pathologies follow divergent pathways. In unclear cases, inspection and pH testing may help to distinguish GI from tracheobronchial hemorrhage. Unless an active, brisk upper GI hemorrhage is present, the acidification of blood in the stomach results in fragmentation and darkening, producing specks of brown or black material often referred to as coffee-ground emesis. Pulmonary blood appears bright red or as only slightly darker clots and is alkaline.

Inflammatory disorders that secondarily involve the lungs or pulmonary vasculature include Wegener’s granulomatosis, Goodpasture’s syndrome, and SLE, and a history of these should be elicited. Any risk factors for platelet dysfunction, thrombocytopenia, and coagulopathy should be noted, as should, conversely, any...
Infections that might contribute to venous thromboembolism include:

- Hypercoagulable states
- Primary or metastatic cancer
- Recent percutaneous or transbronchial procedures
- A history of chronic alcoholism, cancer, or pulmonary fungal infections
- Other chronic conditions such as idiopathic pulmonary fibrosis or Wegener’s granulomatosis

**Pivotal Findings**

**Symptoms**

Although patient reports of bleeding severity can be inaccurate, an estimate of the rate, volume, and appearance of expectorated blood should be obtained. Additional pertinent history includes prior episodes of hemoptysis or parenchymal pulmonary disorders, including bronchiectasis, recurrent pneumonia, chronic obstructive pulmonary disease, bronchitis, TB, and fungal infection.

**Ancillary Testing**

Initial laboratory studies include a complete blood count, coagulation tests, and a type and crossmatch for packed red blood cells. Renal function tests should be performed if vasculitis is suggested or contrast computed tomography (CT) is planned. Plain chest radiography plays a limited role in evaluating patients with minor hemoptysis. Although chest x-rays can screen for causes of hemoptysis (including infection and malignancy), their sensitivity is poor and often cannot identify the source of bleeding. A critical step in triage and management (see the Empirical Management section) is to identify cases of hemoptysis patients with a normal chest radiograph which will have positive findings on chest CT.

When there is massive hemoptysis, plain films localize the site of hemorrhage in as many as 80% of patients; however, high-resolution CT of the chest is the principle diagnostic test for investigating both bronchial and non-bronchial causes of massive hemoptysis. A chest CT scan should be obtained in the high-risk patient (ie, smokers, oncology patients) or in any patient with moderate to severe bleeding even if the initial chest radiograph is normal. CT localization of hemorrhage can expedite bronchoscopic evaluation and guide subsequent interventional procedures.

CT is diagnostically comparable to conventional angiography but less invasive and more rapidly available. Angiography is the first-line study when the cause of the hemoptysis is known (eg, malignancy), bronchial artery hemorrhage is suspected or when angiography-assisted embolization therapy is contemplated. Successful embolization rates range to 95%.

**Diagnostic Algorithm**

**Critical Diagnoses**

Box 21.2 shows critical diagnoses and emergent diagnoses. Proper management hinges not only on standard resuscitative measures but also specific therapies, such as reversal of coagulopathy or emergent surgical intervention. For example, in patients with pre-existing tracheostomies, new hemoptysis (especially within 3 to 4 weeks of surgery) often represents a tracheo-innominate artery fistula (TIF) for which the need for hemorrhage control is immediate and can often be accomplished in the ED.

Although management decisions hinge on the volume and rate of bleeding, the initial diagnostic strategy is the same for all patients with hemoptysis (Fig. 21.1). Patients with trace hemoptysis or blood tinged sputum only and a classic story for viral bronchitis may not require laboratory or radiology investigation of any type. For all others, the initial screening test obtained in the ED is a chest x-ray. Since the advent of high-resolution CT, radiologic evaluation has had an integral role in the evaluation and treatment of patients with hemoptysis. Unless the initial chest radiograph is diagnostic or the patient is hemodynamically unstable, a chest CT should be obtained. Further management decisions should be guided by the CT results and made in conjunction with pulmonary and thoracic surgery consultants.

**Diagnosis of Hemoptysis**

**Airway Disease**

- Bronchitis (acute or chronic)
- Bronchiectasis
- Neoplasm (primary and metastatic)
- Trauma
- Foreign body

**Pulmonary Embolism**

- Pulmonary embolism
- Arteriovenous malformation
- Aortic aneurysm
- Pulmonary hypertension
- Vasculitis (Wegener’s granulomatosis, systemic lupus erythematosus [SLE], Goodpasture’s syndrome)

**Hematologic Disease**

- Coagulopathy (cirrhosis or warfarin therapy)
- Disseminated intravascular coagulation (DIC)
- Platelet dysfunction
- Thrombocytopenia

**Cardiac Disease**

- Congenital heart disease (especially in children)
- Valvular heart disease
- Endocarditis

**Miscellaneous**

- Cocaine
- Perioperative injury
- Tracheal-arterial fistula
- SLE

**Signs**

A targeted examination may suggest the location and cause of bleeding but does so in less than 50% of cases. Focal adventitious breath sounds in a febrile patient may indicate pneumonia or pulmonary abscess. A new heart murmur, especially in a febrile patient, may reflect endocarditis causing septic pulmonary emboli. A rash might hint at underlying rheumatologic disorders, such as SLE or vasculitis. Symptoms and signs of deep venous thrombosis suggest pulmonary embolism. Ecchymoses and petechiae can indicate coagulopathy and thrombocytopenia, respectively.
**Bronchoscopy**

Early bronchoscopy may be the right option because it facilitates both localization of bleeding and therapeutic intervention. Chest CT is as diagnostically accurate as bronchoscopy in locating bleeding peripheral vessels not accessible by a flexible bronchoscope. Chest CT can be used to identify the site of bleeding to determine whether angiography is indicated. There may be little added benefit to bronchoscopy before interventional angiography if the bleeding source has already been accurately identified on CT.

**EMPIRICAL MANAGEMENT**

Figure 21.2 outlines the management algorithm for patients with hemoptysis. Although hemodynamic instability can occur as a result of hemorrhage, the most lethal sequela of massive hemoptysis is hypoxia, which results from the ventilation-perfusion mismatch that follows submersion of the small airways and alveoli with blood.

All patients with massive hemoptysis should have multiple large bore peripheral intravenous lines placed. Volume resuscitation should begin immediately for patients with ongoing bleeding or shock. Coagulopathy, in the setting of severe bleeding, should be reversed by infusing 2 to 4 units of fresh frozen plasma (FFP) and 10 mg of intravenous vitamin K. Prothrombin complex concentrates (PCCs) have been successful in reversing warfarin-induced intracranial hemorrhage, but there is no information to guide the use of PCC in patients with severe hemoptysis.4 Patients with thrombocytopenia should have a platelet transfusion with a goal platelet count of 50,000 to 60,000.

If a TIF is suspected, the emergency clinician should immediately attempt to overinflate the tracheostomy balloon in an effort to tamponade the bleeding. If this fails, the tracheostomy tube should be removed, the patient should be orally intubated, and the operator’s index finger should be placed through the tracheostomy hole with pressure applied at the sight of bleeding (Fig. 21.3).

Aortobronchial artery fistulae are highly lethal; but if caught early, general resuscitative measures should be undertaken in addition to immediate consultation with or transfer to an endovascular surgeon. Pulmonary embolus only rarely affiliated with massive hemoptysis. When trace hemoptysis accompanies pulmonary embolism, usual care with anticoagulation is standard treatment.

Hemoptysis as a complication of disseminated intravascular coagulation (DIC) should be treated following the general management guidelines for DIC. Treatment of DIC remains controversial; but when bleeding is present thrombocytopenia with platelet counts less than 50,000, transfusion is indicated. FFP and cryoprecipitate have been advocated to replace factors lost due to consumptive coagulopathy.

Patients with a known or suspected lateralizing source of bleeding should be placed in the “bleeding lung-down” position such that the bleeding lung is more dependent, promoting continued protection and ventilation of the unaffected lung and improved oxygenation. If intubation is required, a large diameter

**BOX 21.2**

**Critical and Emergent Diagnoses in Patients Presenting With Hemoptysis**

**CRITICAL DIAGNOSES**
- Disseminated intravascular coagulopathy (DIC)
- Tracheo-innominate artery fistula (TIF)
- Aortobronchial fistula
- Iatrogenic (postprocedural) hemoptysis
- Pulmonary embolus

**EMERGENT DIAGNOSES**
- Trauma
- Bronchiectasis
- Pneumonia
- Abscess/fungal infection
- Oral anticoagulant overdose
- Endocarditis

---

**Fig. 21.1.** The emergency department (ED) diagnostic approach to hemoptysis. BNP, B-type natriuretic peptide; CBC, complete blood count; CT, computed tomography; CXR, chest x-ray; D/C, discharge; INR, international normalized ratio; PT, prothrombin time.
simple lung-down positioning is not sufficient to stabilize the patient’s airway and oxygenation.

When these measures fail or the hemoptysis is life-threatening, anesthesia consultation is sought for consideration of placement of double-lumen endotracheal tubes for lung isolation. The correct positioning of blindly placed double-lumen tubes is difficult and requires confirmation by auscultation and fiberoptic bronchoscopy, both of which are severely impaired by massive hemoptysis. Complications of double-lumen tubes include unilateral and bilateral pneumothoraces, pneumomediastinum, carinal rupture, lobar collapse, and tube malposition.

Fiberoptic bronchoscopy, in addition to being one of the first diagnostic maneuvers, is a first line therapeutic option as well. Balloon and topical hemostatic tamponade, thermocoagulation, and injection of vasoactive agents can all effectively control arterial bleeding. Optimal timing for bronchoscopy remains conjectural. Although stable patients with mild to moderate bleeding may benefit from early bronchoscopy, in unstable patients or those with brisk hemorrhage, bronchoscopy may facilitate airway management but is less likely to control bleeding.

Bronchial arterial embolization is an effective first-line therapy for massive hemoptysis and is the procedure of choice for patients either unable to tolerate surgery or in whom bronchoscopy has been unsuccessful. Hemostatic rates range from 85% to 98%, but as many as 20% to 50% of patients have early episodes of repeat bleeding. The risk of delayed bleeding may exist for up to 36 months. To guide therapy, initial localization of bleeding by bronchoscopy or CT is preferred. Rare complications include arterial perforation and dissection.

Emergency thoracotomy, in the operating room, is reserved for life-threatening hemoptysis or for persistent, rapid bleeding that is uncontrolled by bronchoscopy and percutaneous embolization. Although lung resection for massive hemoptysis carries with it high morbidity and mortality, it is a permanent solution to ongoing life-threatening hemoptysis. Pulmonary arterial hemorrhage from tumor necrosis represents a surgical emergency.

Healthy patients with blood-streaked sputum or intermittent small-volume hemoptysis in the context of an acute or subacute respiratory infection with resolved hemoptysis and normal vital signs do not require imaging beyond plain chest radiography and

(8.0) endotracheal tube should be used to facilitate emergent flexible bronchoscopy.

If the patient has marginal hemodynamic status, the intubation should proceed with a “shock-sensitive” strategy focusing on preload maximization with isotonic fluids or blood, reduced dose induction agents and peri-intubation pressors, such as phenylephrine (Neo-Synephrine) (see Chapter 1). In selected cases of confirmed left-sided bleeding, a single-lumen right-mainstem intubation often can be successfully performed through advancement of the tube in the neutral position or use of a 90-degree rotational technique, during which the tube is rotated 90 degrees in the direction of desired placement and advanced until resistance is met. Left-mainstem intubations are more difficult but may be attempted when the bleeding site is the right lung and
can be discharged. High-risk patients (such as, those with known lung cancer, pulmonary vascular abnormalities, or coagulopathy with minor hemoptysis) and all patients with moderate or large amounts of hemoptysis should undergo emergent chest CT scan. There is little value in obtaining a plain chest radiograph before CT, and a plain x-ray film should not be obtained if chest CT is planned regardless of the findings on the plain film. Brief hospitalization or admission to an observation unit for bronchoscopy should be considered. All patients with massive hemoptysis require admission to an intensive care unit and expedited multidisciplinary treatment involving the emergency physician, pulmonologist, and thoracic surgeon.

### KEY CONCEPTS

- Hemoptysis is caused by infection, trauma, cancer, coagulopathy, or as a complication of invasive pulmonary procedures.
- Plain radiographs are the initial screening test in most cases of massive hemoptysis, although CT scans are more sensitive and can supplant plain chest x-rays as the initial diagnostic test.
- Bronchial artery embolization is highly effective with hemostasis rates ranging from 85% to 95%.

- With massive hemoptysis, hypoxia is the more immediate concern than volume resuscitation, and early intubation to ensure adequate oxygenation is paramount.
- If a tracheo-innominate artery fistula (TIF) is suspected, then overinflation of the tracheostomy balloon or digital pressure at the site of bleeding should be performed for immediate hemorrhage control.

CHAPTER 21: QUESTIONS & ANSWERS

21.1. What is the most common cause of trace hemoptysis (blood-tinged sputum)?
A. Bronchiectasis
B. Bronchitis
C. Cancer
D. Congestive heart failure
E. Pulmonary embolism
Answer: B. The most common cause of small-volume hemoptysis is bronchitis.

21.2. Disruption of which of the following vessels is responsible for the vast majority of cases of massive hemoptysis?
A. Aorta
B. Bronchial arteries
C. Pulmonary arteries
D. Pulmonary veins
E. Tracheobronchial capillaries
Answer: B. Massive hemoptysis almost exclusively involves one of the two sets of vessels that constitute the lung's dual blood supply. Bronchial arteries, direct branches from the thoracic aorta, are responsible for supplying oxygenated blood to the lung parenchyma. Disruption of these vessels can result in sudden and profound hemorrhage. Although small in caliber, the bronchial circulation is a high-pressure system and the cause in nearly 90% of the cases of massive hemoptysis requiring embolization. Although they transmit large volumes of blood, pulmonary arteries are at much lower pressure and, unless affected at a very central location, are less likely to cause massive hemoptysis. Trace hemoptysis typically originates from tracheobronchial capillaries that become disrupted with vigorous coughing or minor bronchial infections.

21.3. Which of the following statements regarding the evaluation of hemoptysis is true?
A. Chest computed tomography (CT) should not be obtained in patients with massive hemoptysis if this delays initiation of bronchoscopy.
B. Chest CT should be obtained in any patient with moderate bleeding even if the initial chest radiograph is normal.
C. Conventional angiography is the preferred diagnostic test to detect both bronchial and non-bronchial arterial causes of massive hemoptysis.
D. High-resolution multidetector CT, even with recent advances in technology, remains diagnostically inferior to angiography.
E. In patients with massive hemoptysis, plain films accurately localize the site of hemorrhage in less than 50% of patients.
Answer: B. In patients with massive hemoptysis, plain films may localize the site of hemorrhage in as many as 80% of patients.

However, high-resolution multidetector CT of the chest is the principal diagnostic test to detect both bronchial and non-bronchial arterial causes of massive hemoptysis. CT is diagnostically comparable with, but less invasive than, conventional angiography, which currently is done as a combined diagnostic/therapeutic modality. A chest CT scan should be obtained in high-risk patients (smokers and oncology patients) or in any patient with moderate-to-severe bleeding even if the initial chest radiograph is normal. CT localization of hemorrhage can expedite bronchoscopic evaluation or guide subsequent interventional procedures.

21.4. A 50-year-old man presents after an episode of hemoptysis. He describes coughing up several large clots of dark blood. During his evaluation, he coughs and expectorates approximately 5 mL of clotted blood. The patient’s vital signs are normal, and no abnormalities are noted on physical examination. His chest radiograph is normal. Which of the following is the most appropriate next step in the management of this patient?
A. Admission to an observation unit
B. Consultation for bronchoscopy
C. Consultation for percutaneous embolization
D. Discharge home with follow-up in 24 hours
E. Obtain chest CT scan
Answer: E. Since the advent of high-resolution CT, radiologic evaluation has had an integral role in the evaluation and management of patients with hemoptysis. Unless the initial chest radiograph is diagnostic or the patient is hemodynamically unstable, a chest CT scan should be obtained in most cases. Further management strategy should occur in conjunction with pulmonary and thoracic surgery consultants, guided by the CT results.

21.5. A 58-year-old man with a single lung transplant presents to the emergency department (ED) with what appears to be large-volume hemoptysis. He was just discharged from the endoscopy suite, where he had a number of surveillance biopsies performed. He looks pale and diaphoretic with an initial oxygen saturation of 71%. After placement of an intravenous line and supplemental oxygen, the next most appropriate step is:
A. Blood transfusion
B. Contrast-enhanced CT scan of the chest
C. Intubation
D. Thoracic surgery consultation
Answer: C. This patient is profoundly hypoxic, will need imaging outside of the ED, and invasive procedures. All resuscitative and procedural efforts will be futile without intubation and maximal oxygenation.
## PERSPECTIVE

**Dyspnea** is the term applied to the sensation of breathlessness and the patient’s reaction to that sensation. It is an uncomfortable awareness of breathing difficulties that in the extreme manifests as “air hunger.” Dyspnea is often ill defined by patients, who may describe the feeling as shortness of breath, chest tightness, or difficulty breathing. Dyspnea results from a variety of conditions, ranging from nonurgent to life-threatening. Neither the clinical severity nor the patient’s perception correlates well with the seriousness of underlying pathology and may be affected by emotions, behavioral and cultural influences, and external stimuli. 

The following terms may be used in the assessment of the dyspneic patient:

- **Tachypnea:** A respiratory rate greater than normal. Normal rates range from 44 cycles/min in a newborn to 14 to 18 cycles/min in adults.
- **Hyperpnea:** Greater than normal minute ventilation to meet metabolic requirements.
- **Hyperventilation:** A minute ventilation (determined by respiratory rate and tidal volume) that exceeds metabolic demand. Arterial blood gases (ABGs) characteristically show a normal partial pressure of oxygen (PO$_2$) with an uncompensated respiratory alkalosis (low partial pressure of carbon dioxide [PCO$_2$] and elevated pH).
- **Dyspnea on exertion:** Dyspnea provoked by physical effort or exertion. It often is quantified in simple terms, such as the number of stairs or number of blocks a patient can manage before the onset of dyspnea.
- **Orthopnea:** Dyspnea in a recumbent position. It usually is measured in number of pillows the patient uses to lie in bed (eg, two-pillow orthopnea).
- **Paroxysmal nocturnal dyspnea:** Sudden onset of dyspnea occurring while reclining at night, usually related to the presence of congestive heart failure.

## Epidemiology

Dyspnea is a very common presenting complaint among emergency department (ED) patients of every age. Causes vary widely, and range from benign, self-limited conditions to critical pathology that can produce short-term mortality and long-term morbidity. 

## Pathophysiology

The actual mechanisms responsible for dyspnea are only beginning to be specifically described. Normal breathing is controlled both centrally by the respiratory control center in the medulla oblongata and peripherally by chemoreceptors located near the carotid bodies, but there are numerous sensory inputs that affect the feeling of dyspnea, including pulmonary stretch receptors and mechanoreceptors in the diaphragm and skeletal muscles.

Imbalances among these inputs can be perceived as dyspnea and may manifest as increased work of breathing, due to increased lung resistance or decreased compliance in asthma or chronic obstructive pulmonary disease (COPD). Alternatively, the imbalances of these inputs may also manifest as increased respiratory drive—ie, resulting from severe hypoxemia, acidosis, or centrally acting stimuli (toxins, central nervous system events).

## Diagnostic Approach

### Differential Diagnosis Considerations

Dyspnea is subjective and has many different potential causes. The differential diagnosis can be divided into acute and chronic causes, of which many are pulmonary. Other causes include cardiac, metabolic, infectious, neuromuscular, traumatic, and hematologic conditions (Table 22.1).

### Pivotal Findings

#### Symptoms

Patient descriptions of dyspnea vary significantly and generally correlate poorly with severity, although the complaint of dyspnea alone is predictive of mortality.

- **Duration of Dyspnea:** Chronic or progressive dyspnea usually denotes primary cardiac or pulmonary disease. Acute dyspneic spells may result from asthma exacerbation; infection; pulmonary embolus; intermittent cardiac dysfunction; psychogenic causes; or inhalation of irritants, allergens, or foreign bodies.

- **Onset of Dyspnea:** Sudden onset of dyspnea should lead to consideration of pulmonary embolism (PE) or spontaneous pneumothorax. Dyspnea that builds slowly over hours or days may represent a flare of asthma or COPD; pneumonia; recurrent, small pulmonary emboli; congestive heart failure; or malignancy.

- **Positional Changes:** Orthopnea can result from left-sided heart failure, COPD, or neuromuscular disorders. One of the earliest symptoms seen in patients with diaphragmatic weakness from neuromuscular disease is orthopnea.

or pleural irritation from pneumonia or PE. Spontaneous pneumothorax also may produce sharp pain with deep breathing that is not worsened by movement.

Signs

Physical signs in dyspneic patients may be consistent with specific illnesses (Table 22.2). For example, fever suggests an infectious cause, somnolence or obtundation may indicate hypercarbia, agitation can be associated with hypoxia, and trauma may produce dyspnea through various injuries. Physical findings found in specific diseases also can be grouped according to presenting patterns (Table 22.3). Some findings have improved predictive value for specific pathologies when combined with laboratory testing in validated risk stratification tools.9–11

Ancillary Testing

Specific findings obtained from the history and physical examination should be used to determine which ancillary studies are needed (Table 22.4). Bedside oxygen saturation determinations, or selective use of ABGs when oximetry is not reliable, are useful in determining the degree of hypoxia and the need for supplemental oxygen or assisted ventilation. In patients with abnormal values, a venous blood gas (VBG) is a less painful alternative to ABG to determine pH.12 VBG is less reliable for PCO₂ or accurate numeric correlation to arterial hypercapnia, although a normal venous PCO₂ has a strong negative predictive value, and values greater than 45 mm Hg are highly sensitive in predicting arterial hypercarbia.13,14 The more invasive ABG is useful when an accurate PCO₂ or PO₂ is important. An additional resource for quickly assessing ventilatory status is noninvasive waveform capnography. End-tidal carbon dioxide (ETCO₂) values correlate well with arterial carbon dioxide (CO₂), and the shape of the capnogram can be helpful in assessing the adequacy of ventilations, as well as underlying causes of the dyspnea (see Chapter 5).15 An electrocardiogram may be useful if history or physical examination findings suggest heart failure, ischemic cardiac disease, dysrhythmia, or pulmonary hypertension. Bedside ultrasound is useful to rapidly assess multiple parameters that can focus and guide therapy. For example, thoracic ultrasound can quickly visualize pleural effusion, pulmonary edema with B lines, pneumothorax when “sandy beach” and “comet tail” signs are absent, cardiac dysfunction by evaluating myocardial contractility and estimating ejection fraction (EF), or pericardial effusion and tamponade.16,17 Abdominal ultrasound can assess

intravascular volume by quantifying inferior vena cava size and compressibility.\textsuperscript{11} Extremity ultrasound can reveal deep venous thrombosis.\textsuperscript{12}

Serum electrolytes may confirm metabolic acidosis or a less common cause, such as hypokalemia, hypophosphatemia, or hypocalcemia. A complete blood count may identify severe anemia or thrombocytopenia associated with sepsis. The white blood cell count is not sufficiently sensitive or specific to be of discriminatory value.

Expanded availability of specific blood biomarkers relevant to emergent evaluation of dyspnea provides improved immediate decision support and allows for short- and long-term prognostication.\textsuperscript{13,14} These include cardiac markers and D-dimer assay, which are useful in pursuing causes, such as cardiac ischemia or venous thromboembolic disease. B-type natriuretic peptide (BNP) analysis adds both diagnostic and prognostic value for several causes of dyspnea, including heart failure, PE, and ischemic cardiac disease.\textsuperscript{15}

If venous thromboembolism is suspected, D-dimer testing, with or without chest computed tomographic angiography, duplex venous ultrasonography, or, rarely, ventilation-perfusion scanning, is performed on patients preselected based on clinical decision rules.\textsuperscript{16} If dyspnea is believed to be upper airway in origin, direct or fiberoptic laryngoscopy or a soft tissue lateral radiograph of the neck may be useful.

**DIAGNOSTIC ALGORITHM**

The range and diversity of pathophysiologic conditions that produce dyspnea render a simple algorithmic approach difficult. The primary branch point is the determination of whether the dyspnea primarily is cardiopulmonary or toxic-metabolic in origin. After initial assessment, stabilization and symptom relief in critical patients, findings from the history, physical examination, and ancillary testing are collated to match patterns of disease that produce dyspnea. This process is updated periodically as new information becomes available. Table 22.3 presents recognizable patterns of disease for common dyspnea-producing conditions, along with specific associated symptoms.

**Critical Diagnoses**

Several critical diagnoses should be promptly considered to determine the best treatment options to stabilize the patient. Tension pneumothorax is a critical condition that is diagnosed by history and physical examination. If a dyspneic patient has no breath sounds on one side, ipsilateral hyper-resonance, severe respiratory distress, hypotension, and oxygen desaturation, prompt decompression of presumptive tension pneumothorax is indicated. Jugular venous distension may or may not be apparent and its absence does not rule out the condition. Bedside ultrasonography can confirm pneumothorax in less obvious cases. If dyspnea and stridor indicate upper airway obstruction, early, definitive assessment, and intervention occur in the ED or operating room. Complete obstruction by a foreign body warrants the Heimlich maneuver until the obstruction is relieved or the patient is unconscious, followed rapidly by direct laryngoscopy for foreign body removal. Heart failure and pulmonary edema can produce dyspnea and respiratory failure and require prompt intervention to support ventilation and gas exchange if severe. Significant bronchospasm and wheezing in anaphylaxis require immediate use of parenteral epinephrine in addition to supportive measures. Severe bronchospastic exacerbations of asthma at any age may lead rapidly to respiratory failure and arrest and should receive vigorous attention, including continuous or frequent administration of a beta-agonist aerosol and steroid therapy.\textsuperscript{24} Ultrasound may also be of benefit in rapidly distinguishing between COPD and heart failure, as well as other pathologies.\textsuperscript{17,18} As mentioned earlier, waveform capnography is a valuable adjunct for assessing the severity and determining the cause of respiratory distress. Presumptive anticoagulation or even thrombolytics may be appropriate in patients with suspected significant PE even prior to diagnostic testing.

**Emergent Diagnoses**

Asthma and COPD exacerbations can result in marked dyspnea with bronchospasm and decreased ventilatory volumes.\textsuperscript{19} Sudden onset of dyspnea with a decreased oxygen saturation on room air accompanied by sharp chest pain may represent PE. Dyspnea accompanied by decreased breath sounds and tympany on percussion on one side is seen with spontaneous pneumothorax. Dyspnea associated with decreased respiratory effort may represent a neuromuscular process, such as multiple sclerosis, Guillain-Barré syndrome, or myasthenia gravis. Unilateral rales, cough, fever, and dyspnea usually indicate pneumonia.

Figure 22.1 provides an algorithm for assessment and stabilization of a dyspneic patient. The initial division is based on the degree of breathing effort associated with the symptoms. The most critical diagnoses are considered first, and appropriate intervention undertaken.

All patients experiencing dyspnea, regardless of possible cause, should be promptly evaluated in the treatment area. Bedside pulse oximetry readings should be obtained, and the patient placed on a cardiac monitor. If the pulse oximetry result is less than 94% on room air, supplemental oxygen either by nasal cannula or mask should be considered, depending on the degree of desaturation. In patients with somnolence or obtundation, hypercarbia and respiratory failure should be considered as possible etiologies. If necessary, ventilation should be assisted manually or mechanically, either noninvasively for the short term, or with the patient tracheally intubated for airway protection for prolonged ventilation.\textsuperscript{25}

Decreased mental alertness, inability to speak in more than one-syllable words, or certain types of body positioning signal the presence of significant respiratory distress and the need for rapid intervention. After the airway has been secured, rapid assessment of the patient’s appearance and vital signs can help determine the need for further stabilization and the cause of the dyspnea can be further investigated.

**Empirical Management**

The management algorithm for dyspnea (Fig. 22.2) outlines the approach to treatment for most identifiable diseases. Unstable patients or patients with critical diagnoses must be stabilized and may require admission to an intensive care unit. Emergent patients who have improved with ED management may be admitted to an intermediate care unit. Patients diagnosed with urgent conditions in danger of deterioration without proper treatment or patients with severe comorbidities, such as diabetes, immunosuppression, or cancer, may also require admission for observation and treatment.

Most patients in the nonurgent category can be treated as outpatients if medical follow-up can be arranged. If dyspnea persists despite therapy and no definitive cause has been delineated, the preferred course of action is hospitalization for observation and ongoing evaluation. If no definitive diagnosis can be obtained and the symptoms have abated, the patient may be discharged with medical follow-up and instructions to return if symptoms recur.
Fig. 22.1. Rapid assessment and stabilization of a dyspneic patient. CHAPTER 22  Dyspnea

Dyspnea results from a variety of conditions, ranging from nonurgent to life-threatening. Neither the clinical severity nor the patient’s perception correlates well with the seriousness of underlying pathology.

Dyspnea is subjective and the differential diagnosis can be divided into acute and chronic causes, of which many are pulmonary. Other causes include cardiac, metabolic, infectious, neuromuscular, traumatic, and hematologic conditions.

Chronic or progressive dyspnea usually denotes primary cardiac or pulmonary disease. Acute dyspneic spells may result from asthma exacerbation; infection; pulmonary embolus; intermittent cardiac dysfunction; psychogenic causes; or inhalation of irritants, allergens, or foreign bodies.

All patients experiencing dyspnea, regardless of possible cause, should be promptly evaluated in the treatment area. Bedside pulse oximetry readings should be obtained, and the patient placed on a cardiac monitor.

If the pulse oximetry result is less than 95% on room air, the patient should be placed on supplemental oxygen either by nasal cannula or mask, depending on the degree of desaturation.

If necessary, breathing should be assisted with manual or mechanical ventilation, either noninvasively for the short term, or with the patient tracheally intubated for airway protection for prolonged ventilation.

Unstable patients or patients with critical diagnoses must be stabilized and require admission to an intensive care unit. Emergent patients who have improved in the ED may be admitted to an intermediate care unit. Most patients in the nonurgent category can be treated as outpatients if medical follow-up can be arranged.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Hyperpnea is best defined by which of the following?

A. A respiratory rate greater than normal
B. A tidal volume that exceeds metabolic demands
C. Decreased end-tidal carbon dioxide levels
D. Elevated functional residual capacity
E. Greater-than-the-normal minute ventilation necessary to meet metabolic demands

Answer: E. Hyperpnea is greater-than-the-normal minute ventilation necessary to meet metabolic demands.

Stridor is most likely due to:

A. Bronchospasm
B. Guillain-Barré syndrome
C. Laryngeal edema
D. Malignancy
E. Pulmonary embolism

Answer: C. Stridor is an upper airway noise caused by airway narrowing. Of the given options, stridor is most likely due to laryngeal edema.

A 34-year-old male was struck repeatedly with a pipe in the right chest. He becomes acutely more dyspneic during emergency medical services (EMS) transport and becomes clammy, hypotensive, and more tachycardic on arrival to the emergency department (ED). Examination reveals tachypnea, crepitance, and subcutaneous air over the right chest, with decreased breath sounds. The most appropriate next action is:

A. 1-L intravenous (IV) fluid bolus
B. Needle chest decompression of the right chest
C. Perform portable chest radiograph
D. Provide supplemental oxygen by non-rebreather mask
E. Rapid sequence intubation (RSI) and endotracheal intubation

Answer: B. Needle chest decompression is indicated for management of a likely tension pneumothorax. If ultrasound is immediately available, it can be used to confirm pneumothorax, but in this patient, who is in cardiovascular collapse, immediate intervention is necessary.

A 49-year-old female presents with acute onset of dyspnea. Which of the following findings is most suggestive of a primary cardiac etiology? 

A. Hampton’s hump on chest radiograph
B. Positive amino-terminal pro-B-type natriuretic peptide (NT-proBNP)
C. Positive D-dimer
D. Positive Homans’ sign
E. S1Q3T3 on electrocardiography (ECG)

Answer: B. Positive NT-proBNP. Although this may be positive with heart failure or pulmonary embolism (PE), this is the best choice. S1Q3T3, Hampton’s hump, D-dimer, and Homans’ sign are more associated with PE than primary cardiac etiology.

Chest Pain

James E. Brown

PERSPECTIVE

Approximately 6 million patients visit the emergency department (ED) each year with complaints of chest pain, constituting 9% of all patients seen in EDs in the United States. From 1999 to 2008, the total number of ED patients with noninjury complaints increased by 22%, whereas the percentage of patients with chest pain decreased slightly. Chest pain is a symptom caused by several life-threatening as well as non–life-threatening diseases and has a broad differential diagnosis. It is complicated by a frequent dissociation between intensity of symptoms and signs and seriousness of underlying pathology.

Epidemiology

The epidemiology of the critical diagnoses causing chest pain varies widely. Acute coronary syndrome (ACS), aortic dissection, pulmonary embolism (PE), pneumothorax, pericarditis with tamponade, and esophageal rupture are potentially catastrophic causes of chest pain. These are discussed in the relevant chapters in this text. Chest pain that is atypical or of unclear cause is a daily presentation in virtually every ED—large or small, academic or community, urban, suburban, or rural.

Pathophysiology

Afferent fibers from the heart, lungs, great vessels, and esophagus enter the same thoracic dorsal ganglia. Through these visceral fibers, each organ produces the same indistinct quality and location of pain. The quality of visceral chest pain varies widely and is described as “burning,” “aching,” “stabbing,” or “pressure.” Because dorsal segments overlap three segments above and below a level, disease of a thoracic origin can produce pain anywhere from the jaw to the epigastrium. Radiation of pain is caused by somatic afferent fibers synapsing in the same dorsal root ganglia as the thoracic viscera. This stimulation can confuse the patient’s central nervous system into misperceiving that the pain originates in the arms, shoulders, or neck.

DIAGNOSTIC APPROACH

Differential Considerations

Because of the indistinct nature of visceral pain, the differential diagnosis of chest pain is broad and includes many of the most critical diagnoses in medicine and many nonemergent conditions (Table 23.1).

Rapid Stabilization and Assessment

All patients, except those with obvious benign causes of chest pain, undergo electrocardiography as soon as possible after reporting their pain. The electrocardiogram (ECG) should be read for acute myocardial infarction (MI) by the emergency clinician promptly after it is completed. Patients with positive electrocar-

Ischemic coronary syndrome, whereas progressive onset of pain at rest suggests an acute MI. Pain of sudden onset is more typical with aortic dissection, PE, or pneumothorax. Pain after meals is more indicative of a gastrointestinal cause.

The presence of risk factors for a particular disease is primarily of value as an epidemiologic marker for large population studies (Box 23.1). In the ED, presence of risk factors in an individual patient without established disease has minimal or no effect on the clinical likelihood (pretest probability) of a specific disease process.

**Physical Examination**

Specific findings may be found with a variety of causes (Table 23.3).
Ancillary Studies

The two most commonly performed studies in patients with chest pain are chest radiography and 12-lead electrocardiography (Table 23.4). Electrocardiography should be performed within 10 minutes of arrival in all patients with chest pain or potential angina equivalent in whom myocardial ischemia is a possibility. This generally includes all male patients 33 years and older and female patients older than 39 years who report pain from the umbilicus to the mandible, unless a noncardiac cause is readily apparent. Rapid acquisition of the ECG facilitates the diagnosis of acute MI and expedites the National Heart, Lung, and Blood Institute’s recommended door to treatment times from arrival to percutaneous coronary intervention (PCI) or thrombolytic therapy in acute MI. Patients with a new injury pattern on the ECG (Table 23.5) or new ischemic electrocardiographic changes should have appropriate therapy instituted at this point (Fig. 23.2; see also Chapter 68). An ECG showing right ventricular strain...

Circulation 2014; 130: e344.)
pattern, in the appropriate setting, should raise the clinical suspicion for PE. Diffuse ST segment elevation helps confirm the diagnosis of pericarditis.

Chest radiography is performed for patients with a possibly serious cause of chest pain. Pneumothorax, pneumonia, empyema, and pleural effusion are definitively diagnosed at this point. A wide mediastinum or ill-defined aortic knob increases the clinical suspicion for acute aortic dissection. Pleural effusion, subcutaneous air, or mediastinal air-fluid level may be seen in esophageal rupture. An increased cardiac silhouette may indicate pericarditis or cardiomyopathy.

Pneumomediastinum is seen with esophageal rupture and mediastinitis. A serum D-dimer assay may help discriminate patients with PE from those with a possible gastrointestinal cause. A low serum D-dimer level in a patient without a high pretest probability of PE effectively excludes the diagnosis. Patients with a low pretest probability who meet certain defined criteria do not require further testing (see Chapter 78).

Patients at high pretest probability for PE should undergo diagnostic imaging. High pretest probability warrants initiation of anticoagulation (eg, with heparin or low-molecular-weight heparin) therapy in the ED before the imaging study in the absence of a contraindication.

Patients with suspected thoracic aortic dissection may be evaluated by computed tomography (CT) angiography, transesophageal echocardiography, or magnetic resonance imaging. Selection of the imaging modality depends on the patient’s clinical status and availability of the test modality.

A high-resolution (>64 slice) CT scanner can be used to rule out all the life-threatening causes of chest pain. Although ACS, PE, and thoracic dissection (the so-called triple rule-out) are the causes most commonly discussed, pneumothorax, mediastinitis, and pericardial effusions are also diagnosed with CT.

Laboratory testing is useful in the evaluation of ACS. An elevated troponin level in the correct clinical setting is synonymous with acute MI and is embedded in the universal definition of MI. Troponins (I and T), when elevated, identify patients with ACS who have the highest risk for an adverse outcome. Sensitivity for acute MI at 4 hours is approximately 50%, rising to nearly 100% by 12 hours. Creatine kinase (CK) and CK-MB are used only if determination of the troponin level is unavailable.

### DIAGNOSTIC TABLE

After the patient is stabilized and assessment is completed, the findings are matched to the classical and atypical patterns of the seven potentially critical diseases causing chest pain. This matching process is continuous while the patient is evaluated and the response to therapy is monitored. Any inconsistency in findings with the primary working diagnoses necessitates a rapid review of the pivotal findings and the potential diagnoses (Table 23.6).

### EMPIRICAL MANAGEMENT

The management of ACS is discussed in Chapter 68. Fig. 23.3 outlines the approach to treatment of critical noncardiac diagnoses. Patients with critical diagnoses generally are admitted to the intensive care unit. Patients with emergent diagnoses typically are...

admitted to the hospital, most often on telemetry units. Patients with nonemergent diagnoses are usually treated as outpatients. Hospitalization is required in certain cases, particularly when patients have other comorbid conditions.

Frequently, no definitive diagnosis is established. Any patient with almost any type of chest pain may be having coronary ischemia, PE, or aortic dissection. When a clear pattern does not emerge to allow the emergency clinician to make an alternative diagnosis confidently, or if the pattern of symptoms clearly is not compatible with a serious disorder, such as coronary ischemia, continued evaluation, hospitalization, or observation admission may be the best course.

**KEY CONCEPTS**

- Tension pneumothorax is a clinical diagnosis, treated with needle decompression, followed by tube thoracostomy.
- Patients with suspected ACS are risk-stratified by history, ECG, and troponin levels. Those with ST segment elevation myocardial infarction (STEMI) undergo fibrinolysis or percutaneous transluminal coronary angioplasty (PTCA). Those with non–ST segment elevation myocardial infarction (NSTEMI) do not require immediate PTCA. Those with a nondiagnostic ECG and troponin level are managed with observation.
- Thoracic dissection is diagnosed with CT angiography. The initial management of dissection is with urgent control of heart rate, followed by lowering of blood pressure. Further management, medical or surgical, depends on the location of the dissection.
- Pulmonary embolism is diagnosed using a combination of serum D-dimer measurement and imaging, usually CT angiography. Patients with a low pretest probability and normal D-dimer level do not have pulmonary embolism as the cause of their chest pain presentation.
- Patients with pericardial effusions undergo echocardiography to evaluate for cardiac tamponade. Those with signs of shock may require emergent pericardicentesis.

CHAPTER 23: QUESTIONS & ANSWERS

23.1. A patient presents with the sudden onset of unilateral chest pain, followed almost immediately by respiratory distress. He is noted to have a blood pressure of 75/45 mm Hg, pulse of 130 beats/min, and decreased breath sounds on the right side of his chest. What is the most appropriate initial step in the management of this patient?
A. Administer intravenous (IV) antibiotics.
B. Infuse a 2-L bolus of normal saline.
C. Obtain a chest radiograph.
D. Obtain an electrocardiogram (ECG).
E. Perform a tube thoracostomy.

Answer: E. Tension pneumothorax is a critical diagnosis that must be made and remedied, if present, in the first few moments of the rapid stabilization and assessment phase of any patient encounter. If a patient presents with chest pain, respiratory distress, shock, and unilateral reduction or absence of breath sounds, immediate intervention with needle or tube thoracostomy is required.

23.2. A 65-year-old man with a past medical history of prostate cancer presents with chest pain. His blood pressure is 60/40 mm Hg, and his pulse is 145 beats/min. The ECG shows diffuse ST segment elevation, and cardiomegaly is seen on his chest radiograph. What is the most appropriate first step in the management of this patient?
A. Administration of dobutamine
B. Administration of dopamine
C. Cardiac catheterization
D. Cardiac ultrasonography
E. Thrombolysis

Answer: D. Prompt bedside cardiac ultrasonography would be the most appropriate next step in the management of this patient, who presents with symptoms and signs of pericardial effusion with tamponade. If confirmed by ultrasonography, immediate pericardiocentesis would logically follow in an effort to reverse the signs of shock in this patient. Other signs that could accompany the presentation are low voltage on the ECG and elevated jugular venous pressure on examination.

23.3. A “tearing” sensation is classically described for which of the following causes of chest pain?
A. Aortic dissection
B. Coronary spasm
C. Esophageal rupture
D. Mallory-Weiss tear
E. Pneumothorax

Answer: A. “Tearing” pain that may migrate from the front to back or back to front is classically described in aortic dissection. Descriptions such as “squeezing,” “crushing,” or “pressure” lead to the suspicion of a cardiac ischemic syndrome, although cardiac ischemia can be characterized by nonspecific discomfort, such as “bloating” or “indigestion.” “Sharp” or “stabbing” pain is seen more in pulmonary and musculoskeletal diagnoses. Patients complaining of a burning- or indigestion-type of pain may initially be suspected of having a gastrointestinal cause; however, because of the visceral nature of chest pain, all causes of pain may present with any of the preceding descriptions.

23.4. Uremia is a risk factor associated with which of the following causes of chest pain?
A. Acute coronary syndrome
B. Aortic dissection
C. Pericarditis
D. Pneumothorax
E. Pulmonary embolism

Answer: C. Uremia is a risk factor for the development of pericarditis. Other risk factors associated with the development of pericarditis include infection, autoimmune disease, acute rheumatic fever, recent myocardial infarction or cardiac surgery, malignancy, radiation therapy to the mediastinum, and prior pericarditis.

23.5. A narrow pulse pressure is more closely associated with which of the following diagnoses?
A. Acute myocardial infarction
B. Aortic dissection
C. Pericarditis with effusion
D. Pneumothorax
E. Pulmonary embolism

Answer: A. A narrow pulse pressure is a pivotal finding in the diagnosis of pericarditis with associated pericardial effusion. Other characteristic, but less specific, potential findings in the patient with pericarditis include hypotension, tachycardia, fever, and jugular venous distention (JVD). The more specific finding of pericardial rub is also heard in some patients with pericarditis.

23.6. The finding of Hamman’s sign is most consistent with which of the following?
A. Cholecystitis
B. Mediastinitis
C. Pericarditis

Answer: C. Hamman’s sign is classically described as a “distant” heart sound heard remotely from the chest. It is most commonly associated with pericarditis, where the pericardium is inflamed and thickened, leading to an increased threshold for the transmission of sound waves.
D. Pulmonary embolus
E. Unstable angina

**Answer:** B. Hamman’s sign is an audible systolic “crunch” heard on cardiac auscultation that is produced by the heart moving against air in the mediastinum. This can be heard in conditions such as esophageal rupture, mediastinitis, and pneumomediastinum.

23.7. Right ventricular strain on the ECG of a patient complaining of chest pain would be most consistent with which of the following diagnoses?
A. Acute myocardial infarction
B. Coronary ischemia
C. Coronary spasm
D. Pericarditis
E. Pulmonary embolus

**Answer:** E. In the setting of chest pain, right ventricular strain as evidenced on the ECG is highly suspicious for pulmonary embolus.

23.8. The ECG finding of PR segment depression would be more commonly found in which of the following causes of chest pain?
A. Pericarditis
B. Pulmonary embolus
C. ST segment elevation myocardial infarction (STEMI)
D. Subendocardial infarction
E. Unstable angina

**Answer:** A. The electrocardiographic findings most commonly associated with pericarditis are diffuse ST segment elevation and PR segment depression. The ECG in patients with unstable angina is most often normal or nonspecific. T wave inversion may be seen in these patients. The characteristic ECG findings with subendocardial infarction are T wave inversion and/or ST segment depression in concordant leads. Classic STEMI is manifested electrocardiographically by ST segment elevation (>1 mm) in contiguous leads, a new left bundle branch block (LBBB), or Q waves 0.04 second or more in duration. Many possible electrocardiographic findings are associated with pulmonary embolus, usually manifestations of right ventricular strain.
Abdominal pain is defined as pain felt remotely from its source because peripheral afferent nerve fibers from many internal organs enter the spinal cord through nerve roots that also carry fibers from other locations, as illustrated in Figure 24.2. This confounds interpretation of the location of noxious stimuli for the brain. Both visceral pain and somatic pain can manifest as referred pain. Understanding the pathophysiology of referred pain broadens the differential diagnosis to include adjacent anatomical areas: the thorax for upper abdominal pain, and the hips and retroperitoneum for lower abdominal pain. Examples of referred pain are epigastric pain associated with an inferior myocardial infarction, shoulder pain associated with free peritoneal blood irrigating the diaphragm, pain originating from the hips being experienced as pelvic pain, and lower lobe pneumonia causing upper abdominal pain. Finally, some metabolic disorders and “toxidromes” may manifest with abdominal pain.
**Fig. 24.1.** Differential diagnosis of acute abdominal pain by location. CHF, Congestive heart failure; GERD, gastroesophageal reflux disease; LLL, left lower lobe; RLL, right lower lobe.

**Fig. 24.2.** Common locations of referred pain from abdominal cause.

**Box 24.1**

Patients at Higher Risk for Serious Underlying Disorders

- Age older than 60 years old
- Previous abdominal surgery including obesity surgery
- History of inflammatory bowel disease
- Recent instrumentation (eg, colonoscopy with biopsy)
- Known abdominal/pelvic/retroperitoneal malignancy
- Active chemotherapy
- Immunocompromised, including low dose prednisone
- Fever, chills, systemic symptoms
- Women of childbearing age
- Recent immigrants
- Language or cognitive barrier
DIAGNOSTIC APPROACH

Differential Diagnosis Considerations

The differential diagnosis of abdominal pain is divided into abdominopelvic (intraperitoneal, retroperitoneal, and pelvic) causes (eg, appendicitis, cholecystitis, pancreatitis) and non-abdominopelvic processes (eg, pneumonia, myocardial infarction, ketoacidosis, toxicologic, abdominal wall pain). Table 24.1 lists important potentially life-threatening nontraumatic causes of abdominal pain. This group represents the major causative disorders likely to be associated with hemodynamic compromise and for which early therapeutic intervention is critical. More common emergent conditions that cause abdominal pain are listed in Table 24.2.

Rapid Assessment and Stabilization

Although most patients with abdominal pain do not have hemodynamic instability, patients with vital sign abnormalities require prompt evaluation and resuscitation. Elders and immunocompromised patients may present with normal vital signs despite life-threatening etiologies and, therefore, warrant particular scrutiny. Signs of volume depletion indicate the need for volume replacement, which may be oral or parenteral. Hemodynamic instability caused by conditions such as ruptured abdominal aortic aneurysm, massive gastrointestinal hemorrhage, ruptured ectopic pregnancy, ruptured spleen, and hemorrhagic pancreatitis may necessitate blood or blood product replacement.

Bedside ultrasonography can be used to quickly evaluate patients for free intraperitoneal fluid, volume status, and presence of aortic pathology. Ultrasound assessment is part of the initial physical examination and can be invaluable in guiding treatment and disposition. Early surgical consultation is indicated when there is identified intra-abdominal hemorrhage (hemodynamic compromise plus ultrasound evidence of intraperitoneal fluid), suspected aortic aneurysm rupture, or free air within the peritoneum.

Pivotal Findings

Symptoms

A careful and focused history is central to determining the source of abdominal pain. Language and cultural differences may influence accurate communication and mutual understanding; therefore use of an appropriate medical interpreter is essential key component of evaluation of a non-English speaking patient.

In general, abrupt onset and progressive symptoms and severe pain, especially if accompanied by nausea, vomiting, or diaphoresis, suggest a serious underlying cause. Localization and pain migration also are helpful components of the pain history, because they can highlight specific processes. Diffuse pain, particularly crampy pain that migrates and has periods of minimal or no symptoms, generally is nonsurgical. Poorly localized pain may represent the early visceral component of a surgical process, however, so progression of symptoms is important. Colicky pain is indicative of hollow viscus distention, and duration and time of colic may give clues to the identity of the culprit organ, as displayed in Figure 24.3.

The severity and descriptive nature of the pain are subjective, but a few descriptions are classic, for example:

• The diffuse, severe, colicky pain associated with severe nausea in bowel obstruction
• The “pain out of proportion to examination” (ie, severe pain that is not readily reproduced with palpation) observed in patients with mesenteric ischemia

• The radiation of pain from the epigastrium straight through to the midback, almost invariably accompanied by nausea and vomiting associated with acute pancreatitis
• The radiation of pain to the left shoulder or independent pain in the left shoulder associated with splenic pathology, diaphragmatic irritation, or free intra-peritoneal fluid
• The onset of pain associated with syncope seen in ruptured aortic aneurysm or ruptured ectopic pregnancy

A thorough review of the patient's past medical history and medications frequently provides key information. A history of immunocompromised state or immunosuppressive medications may point to infection. A patient undergoing anticoagulation therapy or taking nonsteroidal antiinflammatory drugs (NSAIDs) may point to gastrointestinal bleeding. Diabetics may be experiencing abdominal pain as a feature of ketoacidosis. A patient undergoing chronic opioid therapy may have constipation or even a bowel obstruction. A patient with previous abdominal surgery may have adhesions with obstruction. Inflammatory bowel disease may lead to fistula, perforation, or abscess.

Signs

The objective evaluation begins with measurement of the vital signs. Significant tachycardia and hypotension are indicators that hypovolemia or sepsis may be present. Tachypnea in the absence of hypoxemia may be an indication of metabolic acidosis from gangrenous viscera or sepsis, or simply a catecholamine-induced reaction to pain. Elevated temperature is associated with intra-abdominal infections. Although important, vital signs may be misleading and should be interpreted in the context of the entire presentation. Tachycardia may develop late for various reasons in hypovolemia. Temperature often is normal in elderly patients with laparotomy-proven intraperitoneal infections, or patients with sepsis also may demonstrate hypothermia.

A thorough abdominal examination is an essential part of evaluating abdominal pain. This requires properly positioning the patient supine and exposing the abdomen. The examination begins with inspection for any signs of trauma, bruising, or skin lesions. Ask the patient to localize the area of maximal tenderness by pointing with one finger, and then examine each quadrant of the abdomen individually, examining the culprit area last.

<tbody>
<tr>
<td>Ruptured ectopic pregnancy</td>
<td>Occurs in females of childbearing age. No method of contraception prevents ectopic pregnancy. Approximately 1 in every 100 pregnancies.</td>
<td>Risk factors include nonwhite race, older age, history of STD or PID, infertility treatment, intrauterine contraceptive device placed within the past year, tubal sterilization, and previous ectopic pregnancy.</td>
<td>Severe, sharp constant pain localized to the affected side. More diffuse abdominal pain with intraperitoneal hemorrhage. Signs of shock may be present. Midline pain tends not to be ectopic pregnancy.</td>
<td>Shock or evidence of peritonitis may be present. Lateralized abdominal tenderness. Localized adnexal tenderness or cervical motion tenderness increases the likelihood of ectopic pregnancy. Vaginal bleeding does not have to be present.</td>
<td>β-hCG testing is necessary in all females of childbearing age (10 to 55 years old); combined with ultrasonography, preferably transvaginal in early pregnancy, usually is diagnostic. FAST examination is useful in evaluating for free fluid in patients with shock or peritonitis.</td>
</tr>
<tr>
<td>Ruptured or leaking abdominal aneurysm</td>
<td>Incidence increases with advancing age. More frequent in men. Risk factors include HTN, DM, smoking, COPD, and CAD.</td>
<td>Exact cause is undetermined. Contributing factors include atherosclerosis, genetic predisposition, HTN, connective tissue disease, trauma, and infection.</td>
<td>Patient is often asymptomatic until rupture. Acute epigastric and back pain is often associated with or followed by syncope or signs of shock. Pain may radiate to back, groin, or testes.</td>
<td>Vital signs may be normal (in 70%) to severely abnormal. Palpation of a pulsatile mass is usually possible in aneurysms 5 cm or greater. The physical examination may be nonspecific. Bruits or inequality of femoral pulses may be evident.</td>
<td>Abdominal plain films are abnormal in 80% of cases. Ultrasound can define diameter and length but can be limited by obesity and bowel gas. FAST examination can be helpful in evaluating for leak by looking for free fluid. Spiral CT test of choice in stable patients.</td>
</tr>
<tr>
<td>Mesenteric ischemia</td>
<td>Occurs most commonly in elders with CV disease, CHF, cardiac dysrhythmias, DM, sepsis, and dehydration. Mortality is 70%. Mesenteric venous thrombosis is associated with hypercoagulable states, hematologic inflammation, and trauma.</td>
<td>20% to 30% of lesions are nonocclusive. The causes of ischemia are multifactorial, including transient hypotension in the presence of preexisting atherosclerotic lesion. The arterial occlusive causes (65%) are secondary to emboli (75%) or acute arterial thrombosis (25%).</td>
<td>Pain can be severe and colicky starting in the periumbilical region and then becomes diffuse. Often associated with vomiting and diarrhea. Sometimes postprandial ie, “mesenteric or abdominal angina.”</td>
<td>Early examination results can be remarkably benign in the presence of severe ischemia. Bowel sounds are often still present. Rectal examination is useful because mild bleeding with positive guaiac stools can be present.</td>
<td>Often a pronounced leukocytosis is present. Elevations of amylase and creatine kinase levels are seen. Metabolic acidosis caused by lactic acidemia is often seen with infarction. Plain radiographs are of limited benefit. CT, MRI, and angiography are accurate to varying degrees.</td>
</tr>
<tr>
<td>Intestinal obstruction</td>
<td>Peaks in infancy and in the elderly. More common with history of previous abdominal surgery.</td>
<td>Adhesions, carcinoma, hernias, abscesses, volvulus, and infarction. Obstruction leads to vomiting, “third spacing” of fluid, or strangulation and necrosis of bowel.</td>
<td>Crampy diffuse abdominal pain associated with vomiting.</td>
<td>Vital signs are usually normal unless dehydration or bowel strangulation has occurred. Abdominal distention, hyperactive bowel sounds, and diffuse tenderness. Local peritoneal signs indicate strangulation.</td>
<td>Elevated WBC count suggests strangulation. Electrolytes may be abnormal if associated with vomiting or prolonged symptoms. Abdominal radiographs and CT are useful in diagnosis.</td>
</tr>
<tr>
<td>Perforated viscus</td>
<td>Incidence increases with advancing age. History of peptic ulcer disease or diverticular disease common.</td>
<td>More often a duodenal ulcer that erodes through the serosa. Colonic diverticula, large bowel, and gallbladder perforations are rare. Spillage of bowel contents causes peritonitis.</td>
<td>Acute onset of epigastric pain is common. Vomiting in 50%. Fever may develop later. Pain may localize with omental walling off of peritonitis. Shock may be present with bleeding or sepsis.</td>
<td>Fever, usually of low grade, is common; worsens over time. Tachycardia is common. Abdominal examination reveals diffuse guarding and rebound. “Board-like” abdomen in later stages. Bowel sounds are decreased.</td>
<td>WBC count is usually elevated owing to peritonitis. Amylase may be elevated; LFT results are variable. The upright radiographic view reveals free air in 70% to 80% of cases with perforated ulcers.</td>

<tr>
<td>Massive gastrointestinal bleeding</td>
<td>More common in older adults ages 40 to 70.</td>
<td>History of peptic ulcer disease, gastritis, or liver disease; prior GI bleeding history. Not typically caused by Mallory-Weiss tears, which typically can occur in the stomach but rarely cause severe bleeding.</td>
<td>Nausea and vomiting typically occur with upper GI bleeds with hallmark coffee-ground or hematemesis; lower GI bleeds associated with poorly localized discomfort and bright red blood per rectum; slow transit can lead to melena.</td>
<td>Non-focal abdominal tenderness; large bleeds may result in tachycardia and hypotension with enough blood loss. Hemoglobin/hematocrit is rarely abnormal in acute, massive bleeds.</td>
<td>Stool or gastric guaiac if there is a question of bleeding; massive bleeds may require emergent consultation by gastroenterology or surgery to intervene.</td>
</tr>
<tr>
<td>Acute pancreatitis</td>
<td>Peak age is adulthood; rare in children and elders. Male preponderance. Alcohol abuse and biliary tract disease are risk factors.</td>
<td>Alcohol, gallstones, hyperlipidemia, hypercalcemia, or endoscopic retrograde pancreatography causing pancreatic damage, saponification, and necrosis. ARDS, sepsis, hemorrhage, and renal failure are secondary.</td>
<td>Acute onset of epigastric pain radiating to the mid-back. Nausea and vomiting are common. Pain disproportionate to physical findings. Adequate volume repletion is important in the initial therapy.</td>
<td>Low-grade fever is common. Patient may be hypotensive or tachypneic. Some epigastric tenderness is usually present. Because pancreas is retroperitoneal organ, guarding or rebound not present unless condition is severe. Flank ecchymosis or periumbilical ecchymosis may be seen if process is hemorrhagic.</td>
<td>Serum lipase is the test of choice. Ultrasound examination may show edema, pseudocyst, or biliary tract disease. CT scan may show abscesses, necrosis, hemorrhage, or pseudocysts. Ultrasound is recommended to assess for gallstones while CT is recommended if severe acute pancreatitis is suspected.</td>
</tr>

<tbody>
<tr>
<td>Acute appendicitis</td>
<td>Peak age in adolescence and young adulthood; less common in children and elders. Higher perforation rate in women, children, and elders and in pregnancy. Mortality rate is 0.1% but increases to 2% to 6% with perforation.</td>
<td>Appendiceal lumen obstruction leads to swelling, ischemia, infection, and perforation.</td>
<td>Epigastric or periumbilical pain migrates to RLQ over 8 to 12 hours (50% to 60%). Later presentations associated with higher perforation rates. Pain, low-grade fever (15%), and anorexia (80%) common; vomiting less common (50% to 70%).</td>
<td>Mean temperature 38°C (100.5°F). Higher temperature associated with perforation. RLQ tenderness (90% to 95%) with rebound (40% to 70%) in majority of cases. Rectal tenderness in 30%.</td>
<td>Leukocyte count is nonspecific and may be normal or elevated. If elevated, may or may not show left shift. Urinalysis may show sterile pyuria. CT is sensitive and specific. US may have use in those with normal body habitus (non-obese), women, pregnancy, and children with RLQ pain.</td>
</tr>
<tr>
<td>Biliary tract disease</td>
<td>Peak age 35 to 60 years old; unlikely in patients younger than 20. Female-to-male ratio of 3:1. Risk factors include multiparity, obesity, alcohol intake, and use of birth control pills.</td>
<td>Passage of gallstones causes biliary colic. Impaction of a stone in cystic duct or common duct leads to cholecystitis or cholangitis.</td>
<td>Crampy RUQ pain radiates to right subscapular area. Prior history of pain is common. May have nausea or postprandial pain. Longer duration of pain favors diagnosis of cholecystitis or cholangitis.</td>
<td>Temperature is normal in biliary colic, elevated in cholecystitis and cholangitis. RUQ tenderness, rebound, and jaundice (less common) may be present.</td>
<td>WBC is count elevated in cholecystitis and cholangitis. Lipase and liver function tests may help differentiate this from gastritis or ulcer disease. US shows wall thickening, pericholecystic fluid, stones, or duct dilatation. Hepatobiliary scintigraphy diagnoses gallbladder function.</td>
</tr>
<tr>
<td>Ureteral colic</td>
<td>Average age for first episode is 30 to 40 years old, primarily in men. Prior history or family history of stones is common.</td>
<td>Family history, gout, Proteus infection. Renal tubular acidosis and cystinuria lead to stone formation.</td>
<td>Acute onset of flank pain radiating to groin. Nausea, vomiting, and pallor are common. Patients are usually writhing in pain.</td>
<td>Vital signs are usually normal. Tenderness on CVA percussion with benign abdominal examination. Urinalysis usually shows hematuria. Noncontrast CT is sensitive and specific. US with fluid bolus useful diagnostically.</td>
<td></td>
</tr>
<tr>
<td>Diverticulitis</td>
<td>Incidence increases with advancing age, affects males more often than females. Recurrences are common.</td>
<td>Colonic diverticula may become infected or perforated or cause local colitis. Obstruction, peritonitis, abscesses, fistulae result from infection or swelling.</td>
<td>Change in stool frequency or consistency commonly reported. LLQ pain is common. Associated with fever, nausea and vomiting; rectal bleeding may be seen.</td>
<td>Fever usually of low grade. LLQ pain without rebound is common. Stool may be heme positive. Results on most tests usually normal. Plain radiographs not indicated. CT is diagnostic, but diagnosis is often made clinically, without imaging.</td>
<td></td>
</tr>
<tr>
<td>Acute gastroenteritis</td>
<td>Seasonal. Most common misdiagnosis of appendicitis. May be seen in multiple family members. History of travel or immunocompromise. Most common GI disease in the United States.</td>
<td>Usually viral. Consider invasive bacterial or parasitic cause in prolonged cases, in travelers, or immunocompromised patients.</td>
<td>Pain usually poorly localized, intermittent, crampy, and diffuse. Diarrhea is key element in diagnosis; usually large volume, watery. Nausea and vomiting usually begin before pain.</td>
<td>Abdominal examination usually nonspecific without peritoneal signs. Watery diarrhea or no stool noted on rectal examination. Fever is usually present.</td>
<td>Usually symptomatic care with antiemetics and volume repletion. Heme-positive stools may be a clue to invasive pathogens. Key is not using this as a “default” diagnosis and missing more serious disease.</td>
</tr>
<tr>
<td>Constipation and obstipation</td>
<td>More common in females, elders, the very young, and patients on narcotics.</td>
<td>Idiopathic or hypokinesis secondary to disease states (low motility) or exogenous sources (diet, medications).</td>
<td>Abdominal pain; change in bowel habits.</td>
<td>Variable, nonspecific without peritoneal signs. Rectal examination may reveal hard stool or impaction. Radiographs may show large amounts of stool. This is a diagnosis of exclusion.</td>
<td></td>
</tr>
</tbody>
</table>

CT, Computed tomography; CVA, costovertebral angle; GI, gastrointestinal; LLQ, left lower quadrant; RLQ, right lower quadrant; RUQ, right upper quadrant; US, ultrasonography; WBC, white blood cell.
Tenderness in one quadrant often corresponds with the location of the diseased organ, which will direct the evaluation (see Fig. 24.1). Some disease processes may manifest with pain that is not exclusively within one specific quadrant, such as the suprapubic pain of a urinary tract infection or the midepigastric pain of a gastric ulcer. Although most patients with proven appendicitis have right lower quadrant abdominal tenderness, some patients, particularly elders, those with immunocompromise, and women with advanced pregnancy do not.

A rectal examination has limited use in the evaluation of abdominal pain, except when there is suspicion of gastrointestinal hemorrhage (which usually is not associated with pain), prostatitis, or perirectal disease. The main utility of the rectal examination is in the detection of melena or heme-positive stool, anal fissures or fistulae, stool impaction, or the empty vault associated with bowel obstruction. Rectal examination has not been shown to improve diagnostic accuracy for any cause of abdominal pain, including appendicitis.

For female patients, abdominal evaluation should include a pelvic examination when there is pain or tenderness below the umbilicus. Findings on pelvic examination help differentiate an abdominal from a pelvic source, thus guiding the selection of imaging modality. Pelvic ultrasound examination is superior to computed tomography (CT) scanning in evaluating uterine and ovarian pathology, whereas CT is superior for evaluation of suspected intra-abdominal pathology. Although the pelvic examination may guide the initial choice of imaging modality, overlap in examination findings is common. For example, a patient with right lower quadrant tenderness may have both right adnexal tenderness and tenderness over McBurney’s point, necessitating exclusion of both appendicitis and tubal or ovarian pathology. The diagnosis felt most likely guides the selection and sequencing of imaging.

In most male patients with abdominal pain, a urogenital examination is important. Diseases such as prostatitis, orchitis, and epididymitis commonly cause abdominal pain in males. Testicular torsion is notoriously under-diagnosed as a cause of lower abdominal pain in adolescents and young men. Furthermore, inguinal hernias are more common in males, with the possibility of strangulation or incarceration in the inguinal canal.

In view of the evolving nature of abdominal pain, repetitive examinations are useful. This is common practice with respect to suspected appendicitis and has improved the diagnostic accuracy in patients with atypical presentations.

Ancillary Testing

Urinalysis and testing for pregnancy are perhaps the most time- and cost-effective adjunctive laboratory tests available. Urinalysis results are interpreted within the context of the patient’s clinical picture. Pyuria, with or without bacteriuria, often may confirm the diagnosis of urinary tract infection but also is present in a variety of other conditions, such as appendicitis. Similarly, hematuria is present in the vast majority of patients with nephrolithiasis but also may be seen with cystitis, a much less serious condition, or renal vein occlusion, a much more serious disorder.

A complete blood count (CBC) is often useful in the evaluation of patients with abdominal pain. Of these, the WBC is the most often referenced, despite its lack of diagnostic accuracy. A WBC count seldom contributes to the correct diagnosis of a patient with abdominal pain and often is misleading. Despite the association of elevated WBC counts with many infectious and inflammatory processes, the WBC count is neither sufficiently sensitive nor specific to be considered a discriminatory test to help establish or exclude a specific cause for the pain. The WBC count is within normal range in a significant percentage of patients with serious (surgical) pathology and may be elevated in patients with benign conditions, including gastroenteritis. The CBC is not entirely without use, however. A depressed WBC count may indicate immunocompromise, reduced hematocrit may indicate blood loss, and thrombocytopenia may identify patients with sepsis, alcoholism, or other disorders. Serum electrolytes, even in the presence of protracted emesis or diarrhea, are frequently normal, but excessive electrolyte losses in vomiting and diarrhea can lead to a contraction alkalosis from excessive chloride and potassium loss, indicating the need for volume replenishment, if that is not otherwise clinically obvious. Blood glucose, anion gap, and serum ketone determinations are useful in distinguishing diabetic ketoacidosis. Ultimately, serum electrolytes are useful adjuncts in assessing the patient but rarely provide a diagnosis.

Liver enzymes and coagulation studies are helpful only in a small subset of patients with suspected liver disease. If pancreatitis is suspected, the most useful diagnostic test is a serum lipase elevated to at least double the normal value. Serum amylase is not as reliable as serum lipase and is no longer used for the diagnosis of acute pancreatitis. Serum lactate levels are elevated in states leading to decreased tissue or organ perfusion, such as sepsis. Lactate often is elevated late in bowel ischemia, but a normal lactate level cannot be used to exclude bowel ischemia.

Plain radiography of the abdomen has limited usefulness in the evaluation of acute abdominal pain and should be performed only when bowel obstruction or a radiopaque foreign body is suspected and there is no intent to obtain a CT scan. For suspected perforated hollow viscus, an upright chest radiograph is a better study than an abdominal film to rapidly assess for free air, but the primary role for a chest radiograph is to exclude or diagnose an intrathoracic cause of the patient’s presentation. CT of the abdomen has become the imaging modality of choice with non-obstructive, non-biliary abdominal pain, and should be the first modality used when imaging is required. The CT scan visualizes both intraperitoneal and retroperitoneal structures and has a high degree of accuracy. When biliary or female reproductive disease is suspected, ultrasound is a superior modality.

CT has increased diagnostic utility in elderly patients for several reasons. The elderly with abdominal pain is significantly more likely to require surgery and have an increased mortality compared with younger adults. Furthermore, evaluation of abdominal pain in elders often is more challenging because of difficulties in history taking, unreliable or variable findings on physical examination (including vital signs), physiologic age-related changes, and comorbid conditions. In the elderly population, CT results change management or disposition decisions in a significant proportion of patients.

Technologic advances have improved image acquisition and resolution, and several studies have shown that intravenous (IV) contrast alone is adequate in the evaluation of most suspected pathologic processes, such as solid organ or bowel wall disease. CT with IV contrast alone also has been shown to be sensitive and specific for the confirmation or exclusion of acute appendicitis. The exclusion of oral contrast in these patients can significantly decrease time to disposition and improve patient satisfaction; however, sensitivity and specificity of all CT studies tends to increase with the addition of different contrast media. In looking for appendicitis, for example, several studies have shown that oral and IV contrast increases sensitivity and specificity, but only marginally above CT without contrast. Oral contrast is more valuable in assessing for ulceration, perforation, or inflammatory bowel disease; and IV contrast is useful in determining inflammation and increased vascularity. Protocols tend to be specific to the machines available at an institution and radiologist preference but should be tailored to getting accurate diagnosis in a time-sensitive fashion.

Controversy also surrounds the use of CT with regard to radiation exposure that patients receive. Several studies have attempted
to quantify the radiation exposure associated with CT, but in reality there is variation in dosage among different types of CT studies and imaging protocols. Studies estimate an abdominal CT with IV contrast to produce a dose of 10 to 50 millisieverts (mSv), enough to increase the estimated lifetime risk of cancer to 1 in 470 in a 20-year-old woman. Although patients may feel more confident when CT imaging was part of their ED evaluation, they typically have a very poor understanding of the radiation dose involved. \(^4\) CT is an important adjunct in ED care, but the decision to scan is carefully weighed against the patient’s history, physical examination findings, age, and gender. In particular, a patient with a history of chronic undifferentiated abdominal pain, multiple previous CT scans, and alternative diagnoses may benefit from observation as opposed to another CT scan.

Bedside transabdominal and transvaginal ultrasonography have emerged as extremely useful adjuncts, decreasing time to diagnosis of life-threatening abdominopelvic conditions. Useful indications are shown in Table 24.3. The results of sonographic examinations are operator dependent, and misdiagnosis can occur because of failure to detect or identify pathology, incorrect identification of normal anatomy as pathologic, or overinterpretation of correctly identified findings (eg, the mere presence of gallstones does not confirm that cholecystitis is the cause of the pain).

**DIAGNOSTIC ALGORITHM**

**Critical Diagnoses**

The differential diagnosis considerations with abdominal pain include a significant number of potentially life- or organ-threatening entities, particularly in the setting of a hemodynamically unstable or toxic-appearing patient. A diagnostic algorithm for initial assessment is shown in Figure 24.4. Severely ill patients require timely resuscitation and expeditious evaluation for potentially life-threatening conditions. A focused history and examination should be conducted, and the patient should be placed in a monitored acute care area well equipped for airway control, quick IV access, and fluid administration. Only then should appropriate diagnostics be initiated (bedside focused assessment with sonography in trauma [FAST], aorta ultrasound assessment, and radiographic, electrocardiographic, and laboratory studies). Table 24.1 lists critical diagnoses that should be considered with abdominal pain in order to facilitate appropriate early diagnosis and treatment.

Women of reproductive age with abdominal pain should undergo pregnancy testing early, and a known pregnancy or a positive result on urine or serum pregnancy testing associated with abdominal pain in the first trimester should be considered to represent an ectopic pregnancy until proven otherwise. If evidence of hemorrhage is present, early obstetric consultation and diagnostic ultrasonography should be prioritized. Bedside transabdominal sonography may identify free intraperitoneal fluid during the evaluation of shock, which generally is sufficient evidence to justify operative intervention in the context of a positive pregnancy test and appropriate history and physical examination findings.

**Emergent Diagnoses**

Despite the limitations already described, the approach to the differential diagnosis of abdominal pain generally is based on the location of maximum tenderness. Figure 24.1 shows locations of subjective pain and maximal tenderness on palpation related to various underlying causes. In women of childbearing age, a positive result on pregnancy testing may indicate ectopic pregnancy, but the entire spectrum of intra-abdominal conditions remains in the differential diagnosis. When the very broad differential diagnosis list is compartmentalized by both history and physical examination, ancillary testing should proceed to either confirm or support the clinical suspicion. Common emergent diagnoses of abdominal pain are listed in Table 24.2.

Despite the significant variety of tests available, close to one half of the patients in the ED with acute abdominal pain will have no conclusive diagnosis. It is incumbent on the clinician to reconsider the extra-abdominal causes of abdominal pain with special consideration in elders and immunocompromised patients, before arriving at the diagnosis of “nonspecific abdominal pain.”

**EMPIRICAL MANAGEMENT**

The main therapeutic goals in managing acute abdominal pain are physiologic stabilization, mitigation of symptoms (eg, nausea and pain), and expeditious diagnosis, with consultation if required. An algorithm for management is presented in Figure 24.5.
CHAPTER 24 Abdominal Pain

There is no evidence to support withholding analgesics from patients with acute abdominal pain to preserve the accuracy of subsequent abdominal examinations; in fact, the preponderance of evidence supports the opposite. Pain relief may facilitate the diagnosis in patients ultimately requiring surgery. In the acute setting, analgesics usually is accomplished with intravenously titrated opioids. IV ketorolac, the only parenteral NSAID available in North America, is useful for both ureteral and biliary colic, as well as some gynecologic conditions, but is not recommended for general treatment of undifferentiated abdominal pain. Ktorolac has been shown to cause increased bleeding times in healthy volunteers and should be avoided in patients with gastrointestinal bleeding or potential surgical candidates.

Aside from analgesics, a variety of other medications may be helpful to patients with abdominal pain. The burning pain caused by gastric acid may be relieved by antacids. Antiemetics can be helpful for nausea and vomiting. The 5-HT antagonists, such as ondansetron, produce excellent results with minimal side-effects. Other agents, such as promethazine, prochlorperazine, or droperidol, also can be useful, but the mixed anticholinergic and antihistamine properties of these medications can cause sedation and extrapyramidal side effects. Extra-pyramidal side effects can be treated, if necessary, with diphenhydramine, benzotropine, or benzodiazepines. Gastric emptying by nasogastric tube with suction is not indicated routinely for patients with small bowel obstruction but may relieve symptoms in those with intractable vomiting.

If intra-abdominal infection is suspected, broad-spectrum antibiotic therapy should be initiated promptly. Abdominal infections are often polymicrobial, and coverage for enteric gram-negative, gram-positive, and anaerobic bacteria is indicated. In the choice of antibiotic or combination, the following should be considered:

- Unless local antibiotic resistance dictates otherwise, a second-generation cephalosporin, such as cefotetan, 2 g, or cefoxitin 2 g; or a quinolone, usually ciprofloxacin, 400 mg, or levofloxacin, 500 mg; is combined with metronidazole, 500 mg, for the initiation of antibiotics in the ED. Alternatively, a non-cephalosporin, β-lactam agent with a β-lactamase antagonist, such as ampicillin-sulbactam, 3 g, piperacillin-tazobactam, 3.375 g, or ticarcillin-clavulanate 3 g, provide excellent gram positive and negative, aerobic and anaerobic coverage and are effective as single agents.
- Many enteric gram-negative bacilli mutate rapidly to produce β-lactamases that are poorly antagonized by specific drug combinations containing clavulanate, sulbactam, or tazobactam. Carbapenems, such as imipenem, 1 g, meropenem, 1 g, or cefepime, 1 g, are preferable for patients who have recently received other antibiotics.

Whether to provide coverage for *Enterococcus* species is a subject of debate, and the decision to treat for these bacteria specifically can be made after consultation. Immunocompromised patients may require antifungal agents (see Chapter 187).

**Disposition**

Because up to 40% of patients with acute abdominal pain receive the diagnosis of nonspecific abdominal pain, decisions regarding disposition are difficult. Categories for disposition may include surgical versus nonsurgical consultation and management, admission for observation, and discharge to home with follow-up.
Before discharge of a patient with an undiagnosed cause of nonspecific abdominal pain, several conditions should be met. The abdominal examination findings should not indicate serious organ pathology or peritoneal irritation, and the patient should have normal or near-normal vital signs. Pain and nausea should be controlled, and the patient should be able to take fluids by mouth. If a patient is to be discharged home without a specific diagnosis, clear instructions should be given and include the following information:

- What to do for relief of symptoms or to maximize chances of resolution of the condition (eg, avoiding exacerbating food or activities, how to take any medications prescribed)
- Under what circumstances, with whom, and how soon to seek follow-up evaluation
- Under what conditions to seek more urgent care or return to the ED

Clinically stable patients may be discharged from the ED with appropriate follow-up care, possibly to include repeated physical examination or additional diagnostic imaging if indicated.

In the case of nonspecific abdominal pain that is considered potentially worrisome, CT scan, observation (ie, in the ED observation unit), or follow-up reevaluation after 12 to 24 hours are all valid options.

**Fig. 24.5.** Management algorithm for abdominal pain.
KEY CONCEPTS

- Certain patients with abdominal pain, including elder patients, women of reproductive age, the immunocompromised, patients with cancer, and those who have undergone prior surgery (especially bariatric surgery) are more likely to harbor a serious diagnosis for their abdominal pain presentation and more often require imaging than their otherwise healthy counterparts.
- Early bedside ultrasound is indicated for patients with signs of shock. Ultrasound may identify aortic aneurysm or free intra-peritoneal blood, indicating the need for rapid surgical intervention.
- The WBC count is non-diagnostic in the evaluation of patients with abdominal pain, and neither elevation nor normal range results should be considered confirmatory of a diagnostic impression.
- Ultrasound is superior to CT scanning for the diagnosis of pain originating in the biliary tract or pelvis. Most abdominal pain can be diagnosed with non-contrast or IV contrast only CT scan.
- Pain medication does not impede diagnosis and should not be withheld during diagnostic evaluation.
- Close to half of all patients with abdominal pain will not get a definitive diagnosis in the ED. Select populations may be suitable for discharge with appropriate close follow-up.
- First line antibiotics for serious intraperitoneal infections should be broad spectrum, including anaerobic coverage, such as piperacillin/tazobactam 3.375 g or ciprofloxacin 500 mg plus metronidazole 500 mg.

CHAPTER 24: QUESTIONS & ANSWERS

24.1. Referred pain from pancreatitis is commonly localized to what anatomic area?

A. Left flank  B. Left shoulder  C. Midback  D. Rectum  E. Right shoulder

Answer: C. Pain from acute pancreatitis is usually localized in the epigastric area and radiates to the midback. Pain from spleen is usually referred to the left shoulder, while a perforated ulcer may refer to the right shoulder. Uterine or rectal pain is commonly referred to the low back.

24.2. Which of the following disease processes does not usually cause colicky pain?

A. Diarrhea  B. Gallstone  C. Intestinal obstruction  D. Pancreatitis  E. Ureteral stone

Answer: D. Colicky pain is described as “waxing and waning” and usually arises from hollow organs, such as the gallbladder, ureters, or small/large intestines. Pain from pancreatitis is usually constant and severe.

24.3. Bedside ultrasonography is helpful in making which of the following diagnoses?

A. Cholecystitis  B. Free intraperitoneal hemorrhage from trauma  C. Hydronephrosis from ureteral stone

Answer: F. All of the above

24.4. What intraabdominal processes are best visualized on ultrasound rather than CT?

A. Biliary and ovarian  B. Biliary and perirectal  C. Gastric and hepatic  D. Hepatic and splenic  E. Ovarian and small bowel

Answer: A. Ultrasonography is more sensitive in detecting biliary pathology, which can be more subtle on CT scans, as well as assessing for flow in ovarian torsion.

24.5. Which of the following populations warrants more careful evaluation for abdominal pain?

A. Immunocompromised patients  B. Patients older than 65 years  C. Patients with a language or communication barrier  D. Patients with prior bariatric surgery  E. Pregnant women  F. All of the above

Answer: F. All of the above patients have been shown to exhibit increased complications and morbidity when presenting with abdominal pain.
CHAPTER 25
Jaundice

Todd Andrew Taylor | Matthew A. Wheatley

PERSPECTIVE

Epidemiology

Jaundice is the manifestation of elevated serum bilirubin; thus an understanding of the metabolism of bilirubin is fundamental for the evaluation and management of the emergency department (ED) patient with jaundice. Recently, hepatitis A and B immunizations have altered the traditional population of patients with jaundice because they have significantly decreased the prevalence of these diseases.

Pathophysiology

Normal Bilirubin Metabolism

Bilirubin is generated from heme products, primarily senescent red blood cells. A small portion is derived from myoglobin and maturing erythroid cells. Within the reticuloendothelial system, heme is oxidized to biliverdin, which is then converted to bilirubin. Unconjugated bilirubin forms a tight but reversible bond with albumin in circulation. It is passively taken into the hepatocytes, where it undergoes glucuronidation and at this point has become conjugated bilirubin. This conjugated fraction is secreted into the biliary system and emptied into the gut. Colonic bacteria metabolize the majority of the bilirubin to urobilinogen and stercobilin. Stercobilin is excreted in the stool (causing the stool to turn brown), and urobilinogen is reabsorbed and excreted in the urine. The remaining conjugated bilirubin is deconjugated and reenters the portal circulation to be taken up again by the hepatocytes (enterohepatic circulation). In the laboratory, conjugated bilirubin and unconjugated bilirubin are reported as direct and indirect fractions, respectively.

Abnormalities in Bilirubin Metabolism

Clinical jaundice is usually not evident until the total serum bilirubin concentration rises above 2.5 mg/dL. It is observed in tissues with high albumin concentrations, for example, the skin and eyes. It is absent in albumin-poor fluids, such as tears or saliva. The physiology of bile metabolism may be altered in three principal areas: (1) overproduction of heme products (hemolysis); (2) failure of the hepatocyte to take up, conjugate, and excrete bilirubin (hepatocellular dysfunction); or (3) obstruction of biliary excretion into the intestine. Unconjugated bilirubin that is not bound to albumin can cross the blood-brain barrier, causing adverse neurologic effects ranging from subtle developmental abnormalities to encephalopathy and death. Conditions that favor the unconbound fraction of unconjugated bilirubin, including hemoysis, hypoalbuminemia, acidemia, and drugs that bind competitively to albumin, increase the risk of neurotoxicity. Conjugated bilirubins are not neurotoxic, although they may indicate serious disease.

DIAGNOSTIC APPROACH

Differential Diagnosis Considerations

The three major diagnostic categories to consider in the patient with jaundice are liver injury or dysfunction (cholestasis), biliary obstructive disorders, and disorders of hemolysis. Figure 25.1 outlines a laboratory-based approach to differentiating among these three categories.

Pivotal Findings

The pivotal findings related to history, physical examination, and ancillary testing are listed in Figure 25.2.

Symptoms

Patients may be asymptomatic at presentation or have nonspecific symptoms, such as pruritus, malaise, or nausea. There are a few symptom complexes that can help narrow the differential diagnosis. Jaundice with abdominal pain suggests biliary obstruction or significant hepatic inflammation. New-onset painless jaundice is the classic presentation for a neoplasm involving the head of the pancreas. Patients may complain of ill-fitting clothing because of weight loss or increasing abdominal girth related to ascites. The patient or caregiver may note subtle personality changes or frank confusion, suggestive of hepatic encephalopathy.

Signs

Pertinent physical examination findings are summarized in Figure 25.2. Examination of the skin and the abdomen is particularly helpful in narrowing the differential diagnosis.

Skin findings can point to acute or chronic liver disease. Jaundice is first apparent sublingually, in the conjunctiva and on the hard palate. From there, it spreads caudally; however, the extent of cephalocaudal progression does not accurately reflect the serum bilirubin concentration. Adequate lighting is necessary to detect the initial presentation of jaundice. Cutaneous findings of chronic liver disease include angiomas, excoriations from pruritus, and caput medusa.

The abdominal examination should begin with a thorough visual inspection. A distended or protuberant abdomen can indicate the presence of ascites. On palpation, an enlarged, tender liver suggests hepatic inflammation or engorgement caused by biliary obstruction. An enlarged nontender liver is concerning for malignant infiltration. A nonpalpable liver can indicate fibrosis caused by cirrhosis. A palpable gallbladder, a rare finding, suggests chronic cholestasis or malignancy. The presence of splenomegaly suggests hemolysis, malignancy, or portal hypertension.

Neurologic examination of the jaundiced patient may show depressed mental status, indicating hepatic encephalopathy or cerebral dysfunction caused by sepsis. Asterixis is a specific finding...
Jaundice

CHAPTER 25

225

Patients with gastrointestinal bleeding will have an elevated ammonia level. This is secondary to the excess nitrogen load from the blood being converted into ammonia by the intestinal bacteria. Both glucose and ammonia metabolism can be altered in the presence of hepatocellular injury, and patients with altered mental status should have these levels determined. The degree of elevation in serum ammonia does not correlate directly with the level of hepatic encephalopathy. Ascitic fluid should be analyzed in patients with new-onset ascites and in those with established ascites but new complaints of fever, abdominal pain, gastrointestinal bleeding, hepatic encephalopathy, hypotension, or renal failure. Cell count and differential diagnosis, albumin, and total protein concentration are sufficient initial screening tests. If the etiology of the ascites is unknown, determining the serum ascites albumin gradient (SAAG) is helpful in determining the cause of ascites. The SAAG value is obtained by taking the albumin level in the ascetic fluid and subtracting it from the albumin level in the serum.

Laboratory Tests

Figure 25.2 lists the laboratory tests that are helpful in the evaluation of a patient with jaundice. Serum gamma-glutamyl transpeptidase (GGT) rises in parallel with alkaline phosphatase in the setting of liver disease. Although alkaline phosphatase also can be elevated in diseases affecting bone or placenta, the concomitant increase in serum GGT or 5'-nucleotidase confirms a hepatic source. A reticulocyte count and evaluation of the peripheral blood smear may identify hemolysis. In cases of unexplained hepatocellular injury, a quantitative acetyaminophen level may be helpful. Hepatitis serologies are indicated when the presentation suggests viral illness. Bedside stool guaiac testing should be considered for the presence of gastrointestinal bleeding, because patients with gastrointestinal bleeding will have an elevated ammonia level. This is secondary to the excess nitrogen load from the blood being converted into ammonia by the intestinal bacteria. Both glucose and ammonia metabolism can be altered in the presence of hepatocellular injury, and patients with altered mental status should have these levels determined. The degree of elevation in serum ammonia does not correlate directly with the level of hepatic encephalopathy. Ascitic fluid should be analyzed in patients with new-onset ascites and in those with established ascites but new complaints of fever, abdominal pain, gastrointestinal bleeding, hepatic encephalopathy, hypotension, or renal failure. Cell count and differential diagnosis, albumin, and total protein concentration are sufficient initial screening tests. If the etiology of the ascites is unknown, determining the serum ascites albumin gradient (SAAG) is helpful in determining the cause of ascites. The SAAG value is obtained by taking the albumin level in the ascetic fluid and subtracting it from the albumin level in the serum.

Laboratory approach to differential diagnosis of jaundice. AIDS, Acquired immunodeficiency syndrome; ALT, alanine aminotransferase; AMS, altered mental status; AST, aspartate aminotransferase; CBC, complete blood count; HELLP, hemolysis, elevated liver enzymes, and low platelets; PT, prothrombin time; PTT, partial thromboplastin time.

A benign hereditary condition characterized by hyperbilirubinemia and jaundice due to inadequate hepatic conjugation of bilirubin. Table 25.1 addresses the clinical stages of hepatic encephalopathy.

the serum. A value of greater than or equal to 1.1 g/dL is found in patients with portal hypertension. There are many causes of portal hypertension, including cirrhosis, liver failure, and heart failure. A value of less than 1.1 g/dL can be found in patients with lupus or pancreatitis. SAAG can diagnose portal hypertension, thereby rapidly narrowing the differential diagnosis.

In the setting of suspected bacterial peritonitis, fluid culture is also necessary; Gram stain is rarely helpful. Abscesses with a polymorphonucleocyte (PMN) count >250/mm³ is an indication for antibiotics (cefotaxime 2 grams). Two sets of blood cultures should be performed for patients with fever and jaundice. If there is evidence of gastrointestinal bleeding with hemodynamic instability or severe anemia, a type and crossmatch should be performed.

**Imaging**

When indicated, abdominal imaging can help narrow the differential diagnosis of jaundice, especially in patients for whom biliary obstruction is a concern. The primary role of imaging is in the characterization of obstructive biliary disease. The first choice of study depends on the clinical presentation. Ultrasonography is generally superior for visualization of the gallbladder and ducts, but both ultrasonography and computed tomography (CT) are highly sensitive in diagnosing obstruction. The choice of imaging procedure depends on the pretest probability that there is biliary obstruction and that the obstruction is malignant. For patients with painless, progressive jaundice and without suspicion of hepatocellular injury (eg, hepatitis, alcoholism), malignant obstruction has a high pretest probability, so CT is the preferred method owing to its improved sensitivity in locating the site of the obstruction, determining resectability, and assessing for disseminated disease. Patients with a high likelihood of biliary disease and benign obstruction are best screened with ultrasonography. Ultrasonography is less expensive and less invasive than either magnetic resonance cholangiography or endoscopic ultrasound but has a lower sensitivity in identifying common bile duct stones.²

Ultrasonography with Doppler flow can detect obstruction in the hepatic, portal, and splenic veins. Sonographic features of cholecystitis are discussed in Chapter 90. In patients with low or intermediate clinical likelihood of mechanical obstruction, ultrasonography is the preferred initial modality to evaluate whether or not biliary obstruction is present. CT is preferred if the entire abdomen needs to be evaluated.
CHAPTER 25  Jaundice

The identification of critical or emergent causes of jaundice requires the clinician to recognize patterns in the patient’s signs, symptoms, and ancillary testing. For instance, patients with a triad of jaundice, encephalopathy, and coagulopathy (international normalized ratio [INR] >1.5) have acute hepatic failure. Fever, right upper quadrant pain, and jaundice can indicate biliary obstruction with infection (eg, cholangitis, cholecystitis, or hepatitis). Ascites with abdominal tenderness raises suspicion for spontaneous bacterial peritonitis (SBP). Rapid onset of hepatomegaly and ascites can point to portal vein thrombosis (Budd-Chiari syndrome).

EMPIRICAL MANAGEMENT

General supportive and specific therapies depend on the presumptive cause of the jaundice (Fig. 25.3). If coagulopathy is known or suspected, compressible sites and ultrasound guidance should be used for central venous access. Coagulopathy in the context of acute hemorrhage should be corrected with fresh frozen plasma, and blood volume repletion accomplished with packed red blood cells.

If ascites is present and SBP is suspected, paracentesis is diagnostic. The presence of more than 250 polymorphonuclear cells per cubic millimeter of ascitic fluid is diagnostic for SBP. The empirical antibiotic of choice is a third-generation cephalosporin (eg, cefotaxime). If the patient has a history of cirrhosis and is taking a nonselective beta blocker, it should be discontinued because it has been shown to increase mortality in patients with SBP.

Patients with jaundice and transaminases out of proportion to elevation of alkaline phosphatase have a hepatocellular injury pattern. Treatment of hepatic encephalopathy is described in Chapter 90. Patients with fulminant hepatic failure should be admitted to the intensive care unit or transferred to a hospital with expertise in severe liver disease. Acetaminophen toxicity and indications for N-acetylcysteine therapy are discussed in Chapter 148. There is some evidence suggesting N-acetylcysteine offers a mortality benefit in non-acetaminophen induced acute liver failure. However, the evidence is weak and we do not recommend its use in this context.

In the absence of liver failure, patients with encephalopathy, coagulopathy, or unstable vital signs should be admitted. There are no clear guidelines to indicate what level of hepatic or biliary dysfunction requires inpatient management. We recommend hospitalization or placement into observation status for patients with new-onset jaundice and transaminases approaching 1000 IU/L, bilirubin approaching 10 mg/dL, or evidence of coagulopathy, because these laboratory abnormalities suggest significant hepatic dysfunction. Patients with hepatitis or cholestatic jaundice may be managed as outpatients if they have a normal mental status, stable vital signs, ability to take oral fluids, no evidence of acute bleeding or significant coagulopathy, and no complicating infectious process. Intravenous fluids and antiemetics may be required in the ED. Alcohol and medications with potential hepatotoxicity, particularly acetaminophen, should be avoided.

Fever, abdominal pain, and obstructive jaundice suggest ascending cholangitis (Fig. 25.4). Antibiotic recommendations for ascending cholangitis are discussed in Chapter 90. In addition to antibiotics, patients should be resuscitated with intravenous fluids as necessary and have any metabolic derangements corrected. Because biliary excretion of most antibiotics is compromised in the setting of obstruction, all patients will require biliary

CHAPTER 25 Jaundice

Patients with confirmed or suspected choledocholithiasis, stones in the common bile duct, require admission for possible ERCP or cholecystectomy. Neither CT nor ultrasonography is 100% sensitive in identifying a common bile duct stone, but they are reasonably sensitive in identifying a dilated common bile duct, which is highly suggestive of obstruction.

In patients with anemia, the management is based largely on the etiology. In immune-mediated hemolytic anemia, the decision to transfuse should be based on the patient's ability to oxygenate and the ability to institute alternative treatments. An urgent hematology consultation is recommended (see Chapter 121). In the case of drug-induced hemolytic anemia, the mainstay of treatment involves removal of the offending agent. For patients with glucose-6-phosphate deficiency, blood transfusions are rarely indicated, and the focus of management should be on avoiding oxidative stressors and maintaining urine output to prevent renal failure. Patients with hemoglobinopathies rarely require transfusion therapy unless they have severe anemia without evidence of reticulocytosis. Fluids, oxygen, and analgesics can be given for an acute crisis.

In general, patients with uncomplicated cholecystitis should receive intravenous fluids in the ED, parenteral analgesics and antiemetics as needed, and should be hospitalized. Antibiotic therapy for acute cholecystitis is discussed in Chapter 90. These patients should undergo emergent imaging and consultation with a surgeon or gastroenterologist.

**KEY CONCEPTS**

- Clinical jaundice is usually not evident until the total serum bilirubin concentration rises above 2.5 mg/dL.
- Bile metabolism may be altered when there is an overproduction of heme products (hemolysis); failure of the hepatocyte to take up, conjugate, and excrete bilirubin (hepatocellular dysfunction); or obstruction of biliary excretion into the intestine.
- Unconjugated bilirubin that is not bound to albumin can cross the blood-brain barrier, causing adverse neurologic effects; conjugated bilirubin is not neurotoxic.
- New-onset painless jaundice is the classic presentation for a neoplasm involving the head of the pancreas.
- Jaundice is first apparent sublingually, in the conjunctiva and on the hard palate.
- In cases of unexplained hepatocellular injury, a quantitative acetaminophen level may be helpful.

- If the etiology of the ascites is unknown, getting the serum ascites albumin gradient (SAAG) will aid in determining the cause of ascites and presence of portal hypertension.
- Ultrasonography is the preferred initial modality to evaluate whether or not biliary obstruction is present, whereas CT is preferred if malignant obstruction is suspected or the entire abdomen needs to be evaluated.
- Elevated direct bilirubin with transaminase elevation is indicative of hepatocellular inflammation or injury.
- Diagnosis of spontaneous bacterial peritonitis (SBP) is >250 neutrophil count. Treatment is cefotaxime 2 grams.
- Hyperemesis gravidarum can elevate liver enzymes up to 20 times the normal amount, including mildly elevated bilirubin.
- Intrahepatic cholestasis of pregnancy is an idiopathic cause of jaundice that occurs in the third trimester.

CHAPTER 25: QUESTIONS & ANSWERS

25.1. A 56-year-old male presents with fever, distended abdomen, and a bedside ultrasound that shows ascites. A paracentesis is performed and the results indicate that the patient has spontaneous bacterial peritonitis (SBP). What daily medication should be stopped upon admission?
A. Amlodipine
B. Crestor
C. Lactulose
D. Metoprolol

Answer: D. Beta Blocker use in pts with cirrhosis with SBP should be discontinued because it has been shown to increase mortality.

25.2. A 43-year-old female presents with 1 month of abdominal swelling. On examination she has a diffusely swollen abdomen with a fluid wave. The patient appears to have new onset ascites. In order to help determine the etiology, you obtain the serum ascites albumin gradient (SAAG). Which value is consistent with cirrhosis?
A. 0.25 g/dL
B. 0.5 g/dL
C. 1 g/dL
D. 1.5 g/dL

Answer: D. A (SAAG) value of greater than or equal to 1.1 g/dL is found in patients with portal hypertension. There are many causes of portal hypertension, including cirrhosis, liver failure, and heart failure.

25.3. A 48-year-old male with a history of cirrhosis presents with 3 days of abdominal pain and fever. On examination, he is febrile and has an abdominal examination that is diffusely tender with guarding. The decision is made to do a paracentesis to evaluate for spontaneous bacterial peritonitis (SBP). What is the best treatment for SBP?
A. Cefotaxime and discontinue beta blockers
B. Ceftriaxone and dexamethasone
c. Ceftriaxone and discontinue beta blockers
D. Ciprofloxacin and metronidazole

Answer: A. The empirical antibiotic of choice is a third-generation cephalosporin (eg, cefotaxime). If the patient has a history of cirrhosis and is taking a nonselective beta blocker, it should be discontinued because it has been shown to increase mortality in patients with SBP.

25.4. A 41-year-old male with a history of cirrhosis presents with fever, abdominal distension, and confusion. A paracentesis is performed in the evaluation of spontaneous bacterial peritonitis (SBP). What is the diagnostic criteria found in the ascetic fluid that confirms SBP?
A. Neutrophil count >100
B. Neutrophil count >250
C. WBC >100
D. WBC >250

Answer: B. The presence of more than 250 polymorphonuclear cells per cubic millimeter of ascitic fluid is diagnostic for SBP.

25.5. A 55-year-old female presents with 1 month of diffuse abdominal swelling and pain. She reports a long history of alcohol use. In the evaluating this patient for jaundice, how high does the bilirubin have to be become clinically apparent, and what area of the body does jaundice appear first?
A. 2 mg/dL; nail beds
B. 2 mg/dL; sclera
C. 2.5 mg/dL; skin
D. 2.5 mg/dL; sublingual

Answer: D. Clinical jaundice is usually not evident until the total serum bilirubin concentration rises above 2.5 mg/dL. Jaundice is first apparent sublingually, in the conjunctiva and on the hard palate.

Nausea and Vomiting

Joshua Guttman

PERSPECTIVE

Nausea and vomiting are most commonly associated with primary gastrointestinal (GI) disorders but may also occur with systemic conditions. Nausea and vomiting may be of benign origin or may be associated with life-threatening conditions, and treatment is directed both at symptomatic relief and at the underlying cause. Vomiting may also result in serious sequelae (Table 26.1). Classification by duration and frequency of the vomiting (acute, recurrent, chronic, or cyclic) may assist in determination of the underlying cause.

Epidemiology

Nausea and vomiting represent 4% of emergency department (ED) chief complaints and often are present in patients whose chief complaint is abdominal pain, among many other conditions. The most common causes of nausea and vomiting are GI disorders. Nausea and vomiting may also represent disorders outside the GI tract, such as hyperemesis gravidarum, intracranial lesions and infections, myocardial infarction, diabetic ketoacidosis, and drug toxicities.

Pathophysiology

The act of vomiting is divided into three phases: nausea, retching, and actual vomiting. Nausea may occur without retching or vomiting, and retching may occur without vomiting. The exact neural pathways mediating nausea are not clear, but they are likely to be the same pathways that mediate vomiting. Mild activation of the pathways may result in nausea, whereas more intense stimulation results in vomiting. During nausea there is an increase in tone in the musculature of the duodenum and jejunum, with a concomitant decrease in gastric tone; this leads to reflux of intestinal contents into the stomach. There is often associated hypersalivation, repetitive swallowing, and tachycardia.

Retching is characterized as rhythmic, synchronous contractions of the diaphragm, abdominal muscles, and intercostal muscles that occur against a closed glottis, without the expulsion of gastric contents.

Vomiting is the forceful expulsion of gastric contents through the mouth. There is contraction of the external oblique and abdominal rectus muscles, and the hiatal portion of the diaphragm relaxes; this increases the pressure in the abdominal and the thoracic compartments. There is contraction of the pyloric portion of the stomach. Simultaneously, there is relaxation of the gastric fundus, cardia, and upper esophageal sphincter as the vomitus is brought up and out the mouth. The glottis closes to prevent aspiration.

The complex act of vomiting is coordinated by the vomiting center located in the lateral reticular formation of the medulla. The efferent pathways from the vomiting center are mainly through the vagus, phrenic, and spinal nerves (Fig. 26.1). These pathways are responsible for the integrated response of the diaphragm, intercostal muscles, abdominal muscles, stomach, and esophagus. The vomiting center is activated by afferent stimuli from a variety of sources. These include (1) visceral afferent impulses directly from the GI tract; (2) visceral afferent impulses from outside the GI tract, including the biliary system, peritoneum, pharynx, genitalia, and heart; (3) extramedullary central nervous system (CNS) afferents, including the vestibular system; and (4) the chemoreceptor trigger zone (CTZ) (Fig. 26.2), which is located in the area postrema, the floor of the fourth ventricle. Part of this area is located outside of the blood-brain barrier, enabling it to respond to endogenous and exogenous substances that activate vomiting (see Fig. 26.2).

The discovery of various neurotransmitters and their receptor sites within the medulla has improved the understanding and development of therapeutic agents. The CTZ area is rich in dopamine D₂ receptors and serotonin receptors, and the lateral vestibular nucleus is rich with cholinergic and histamine receptors. Serotonin receptors are also widely found in the GI tract. These receptor sites are targets for the various medications that are used to treat nausea and vomiting.

DIAGNOSTIC APPROACH

Differential Diagnosis Considerations

The differential diagnosis for nausea and vomiting is particularly broad in scope; almost any organ system can be involved. Acute vomiting is defined as episodic vomiting that occurs for less than 1 week and is associated with acute conditions, whereas chronic vomiting, which occurs for a period longer than 1 week, is associated with motility disorders, effects of systemic treatments (such as for cancer), neuropsychiatric conditions (eg, bulimia) and neurologic conditions. Discrete episodes of intractable vomiting with intervening asymptomatic periods are considered cyclic. Common causes of nausea and vomiting are outlined in Table 26.2, and a differential diagnosis is presented in Tables 26.3 and 26.4.

Pivotal Findings

Symptoms

A thorough history, including past medical history, medications, and social history will generally elicit the etiology of vomiting. The content and color of the vomitus may help determine its cause (Table 26.5). Although coffee ground emesis usually suggests a slower bleeding rate than bright red blood, this cannot be relied upon in all cases. The history should be directed at assessing for both the causes of vomiting, as well as its sequelae.

Timing and duration of the vomiting may be important. Symptoms occurring primarily in the morning may suggest increased intracranial pressure. Delayed vomiting more than 1 hour after eating suggests gastric outlet obstruction or gastroparesis. Vomiting of material eaten more than 12 hours previously is pathognomonic for outlet obstruction.

Associated symptoms are helpful: Vomiting with diarrhea is generally due to an infectious gastroenteritis but may also be

GI, Gastrointestinal.

Nausea and vomiting present in mesenteric ischemia or other GI surgical emergencies. Vomiting with abdominal pain is generally caused by diseases of the GI system. Chronic headaches with nausea and vomiting should raise suspicion of elevated intracranial pressure. Vomiting without preceding nausea is typical of CNS pathology. The social history should include inquiries about alcohol or other substance use. The past medical history will reveal the presence of any GI disease or previous surgeries. Finally, a thorough medication list, including over-the-counter drugs and supplements, should be elicited.

A history of similar episodes should be elicited. A history of stereotypical episodes of nausea and vomiting lasting hours to days, with symptom-free intervals may lead to a diagnosis of cyclic vomiting syndrome. In patients with a history of cyclic vomiting, heavy, chronic use of cannabis is important to elicit, because it may lead to a diagnosis of cannabis hyperemesis syndrome. Symptoms are similar to cyclic vomiting syndrome; however, patients will note temporary relief with a hot shower. Onset of the syndrome is often delayed years after chronic marijuana use has begun.

Signs
The examination should begin with an overall assessment of the patient’s status, including an assessment for volume depletion. The history will direct the examination to the appropriate body systems (Table 26.6). The eye examination may reveal nystagmus, which may indicate cerebellar pathology, peripheral vertigo, or drug intoxication. Oral examination may reveal loss of dental enamel commonly seen with bulimia. Abdominal examination, with appropriate testing for occult blood in the stool, may reveal ascites, distention, hernias, abdominal tenderness and masses, or hyperactive or hypoactive bowel sounds. Neurological examination (including funduscopic examination) may be important if a central cause is considered. Provocative testing in patients with suspected benign paroxysmal positional vertigo may elicit vomiting or nystagmus, suggesting this diagnosis (see Chapter 16). Symptoms of depression or anxiety may suggest a psychiatric origin to the vomiting; however, this is a diagnosis of exclusion and rarely is made in the ED.

Ancillary Studies
Testing is determined by the differential diagnosis based on the history and physical examination:
- Serum electrolytes and creatinine: Measurement of serum electrolytes and creatinine is not indicated in most cases of vomiting. Patients with a history of prolonged or severe vomiting, or with clinical evidence of dehydration requiring volume replacement, should undergo electrolyte testing to assess for hypokalemia, hypochloremia, contraction alkalosis, or other sequelae of protracted vomiting. Creatinine may help assess pre-renal dysfunction.
- Serum lipase: Lipase determination is indicated in cases of suspected pancreatitis, based on the patient’s complaint of (often severe) epigastric pain and the presence of tenderness.
- Urine tests: A urine pregnancy test should be performed in all women of childbearing age with nausea and vomiting. A urine analysis may show leukocyte esterase and nitrites as evidence of an urinary tract infection. Ketones may support a diagnosis of diabetic ketoacidosis or prolonged starvation state. Hematuria indicates a possible renal calculus.
- Liver function and ammonia tests: Liver function tests are indicated in cases of suspected hepatitis or biliary disease. Ammonia testing is useful if liver failure is suspected.
- Serum drug levels: Serum drug levels may be important in determining the cause of nausea and vomiting in patients on digoxin, salicylates, or acetaminophen, especially in elders who are taking medication without supervision. Specific serum drug levels should be drawn only if knowledge of the drug level would alter the patient’s management.
- Ultrasound: A bedside abdominal ultrasound evaluates for cholelithiasis, cholecystitis, renal colic, appendicitis, and small bowel obstruction (SBO). Additionally, an assessment of the inferior vena cava may be helpful in monitoring patients with suspected dehydration.
- Abdominal computed tomography (CT): Abdominal CT scan is indicated in patients with a suspected SBO or surgical cause, such as appendicitis, when not diagnosed by ultrasound.
- Cranial imaging: CT or magnetic resonance imaging (MRI) may be indicated to evaluate for intracranial etiologies of nausea and vomiting. When occipital headache is accompanied by hypertension and vomiting, a CT or an MRI should be obtained to evaluate for cerebellar hemorrhage. For other posterior fossa pathologies, such as cerebellar infarction, MRI is preferred.
- Chest imaging: A chest x-ray may reveal subdiaphragmatic air in a patient with a perforated viscus, but abdominal CT is far superior when perforation or other serious intra-abdominal pathology is suspected. For patients with suspected Boerhaave’s syndrome, a chest radiograph is used to assess for a pneumomediastinum, but, again, CT is the preferred modality when this condition is suspected.
If the patient is stable, a more thorough history and physical examination is performed. Empirical therapy, laboratory and radiologic testing are directed by results of the history and examination. Patients with volume depletion requiring IV replacement require serum electrolyte and renal function determination. In addition, patients with associated severe abdominal pain receive IV analgesics and antiemetics as needed, and have additional blood sent for liver function tests and lipase. If sepsis or shock is considered, obtain a serum lactate level. Most patients with severe pain and tenderness will require abdominal imaging. Patients with a history of abdominal surgery and decreased stool output are evaluated for SBO. Patients with severe headache or neurological deficits (not thought to be due to a primary headache disorder)
### TABLE 26.2
Disorders Commonly Associated With Vomiting

<table>
<thead>
<tr>
<th>DISORDER</th>

<th>HISTORY</th>
<th>PREVALENCE</th>
<th>PHYSICAL EXAMINATION</th>
<th>USEFUL TESTS</th>
<th>COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nausea and vomiting of pregnancy (NVP)</td>
<td>Acute</td>
<td>Vomiting may occur in the morning or throughout the day. Associated breast tenderness. NVP typically starts in weeks 4 to 7, peaks in weeks 10 to 16, and disappears by week 20. Vomiting that begins after week 12 or continues past week 20 should prompt a search for another cause.</td>
<td>Very common Affects 75% of all pregnancies</td>
<td>Benign abdomen</td>
<td>Urine pregnancy test Serum electrolytes, urine ketones to exclude hyperemesis gravidarum</td>
<td>Consider NVP in all females of childbearing age. Prognosis for mother and infant is excellent. NVP is associated with a decreased risk of miscarriage, fetal growth retardation, and fetal mortality.</td>
</tr>
<tr>
<td>Hyperemesis gravidarum</td>
<td>Acute</td>
<td>Severe, protracted form of NVP. No universally accepted definition of the disease. Generally accepted hallmarks include 5% weight loss, ketonuria, and electrolyte disturbance. Hyperemesis is associated with multiple gestation, molar pregnancy, and nulliparity.</td>
<td>Uncommon Affects &lt;1% of pregnancies</td>
<td>Signs of dehydration Benign abdomen</td>
<td>β-hCG Urinalysis for ketones Serum electrolytes Ultrasound examination to exclude molar pregnancy or multiple gestations (if not already performed this pregnancy)</td>
<td>Most studies have found no adverse outcomes for the fetus. A few studies however, have shown a correlation with fetal growth retardation.</td>
</tr>
<tr>
<td>Gastroenteritis</td>
<td>Acute</td>
<td>Fever, diarrhea, and crampy abdominal pain. Vomiting and pain occur early, usually followed by diarrhea within 24 hours.</td>
<td>Very common</td>
<td>Benign abdomen</td>
<td>Usually not necessary</td>
<td>Early gastroenteritis, when only vomiting and periumbilical pain are present, may be confused with early appendicitis. Diarrhea is usually in the diagnosis of gastroenteritis.</td>
</tr>
<tr>
<td>Gastritis</td>
<td>Acute</td>
<td>Epigastric pain, belching, bloating, fullness, heartburn, and food intolerance. Use of NSAIDs or ETOH common.</td>
<td>Very common</td>
<td>Mild epigastric tenderness may be present.</td>
<td>Lipase and pregnancy test may be necessary to exclude other diagnoses Removal of inciting agent along with antacid therapy will resolve symptoms in most patients.</td>
<td></td>
</tr>
<tr>
<td>Peptic ulcer disease (PUD)</td>
<td>Acute</td>
<td>Epigastric pain present in 90% of cases. Classically, duodenal ulcer pain is relieved by food, whereas gastric ulcer pain is made worse. Presence of severe pain should raise suspicion of perforation.</td>
<td>Very common</td>
<td>Mild epigastric tenderness</td>
<td>Hemoglobin and hemoccult testing if bleeding is suspected Upright abdominal film if perforation is suspected</td>
<td>Three major causes of PUD are NSAIDs, Helicobacter pylori infection, and hypersecretory states.</td>
</tr>
<tr>
<td>Biliary disease</td>
<td></td>
<td>Abdominal pain may be midepigastric or RUQ. Onset frequently after a fatty meal. May have history of similar episodes in the past.</td>
<td>Very common</td>
<td>RUQ tenderness present in most cases. If instructed to breathe deeply during palpation in the RUQ, the patient experiences heightened tenderness and inspiratory arrest (Murphy’s sign).</td>
<td>WBCs Lipase Serum bilirubin LFTs RUQ ultrasound examination</td>
<td>Normal temperature, WBCs, and spontaneous resolution of symptoms suggest biliary colic. Fever, Murphy’s sign, elevated WBCs, and suggestive ultrasound indicate cholecystitis.</td>
</tr>
<tr>
<td>Myocardial infarction (MI)</td>
<td>Acute</td>
<td>Patients typically have substernal chest pain that may radiate to left arm or jaw. Often associated with dyspnea, diaphoresis, or dizziness.</td>
<td>Common</td>
<td>Patients often are anxious and in distress from pain. No diagnostic examination findings.</td>
<td>ECG (new Q waves, ST segment changes, or T wave inversions) troponin</td>
<td>Not all patients have chest pain. A subset of patients, particularly diabetics and elders, may have only nausea, vomiting, and epigastric discomfort.</td>
</tr>

<th>DISORDER</th>
<th>CLASS</th>
<th>HISTORY</th>
<th>PREVALENCE</th>
<th>PHYSICAL EXAMINATION</th>
<th>USEFUL TESTS</th>
<th>COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Diabetic ketoadiabetes (DKA)</td>
<td>Acute</td>
<td>Polydipsia and polyuria occur early. Without treatment, altered mental status and coma may develop. In patients with long-standing diabetes, DKA may be triggered by infection, change in medication trauma, MI, or surgery.</td>
<td>Common</td>
<td>“Fruity” breath odor results from serum acetone. Tachypnea occurs with attempts to “blow off” carbon dioxide to compensate for metabolic acidosis. Signs of dehydration may be present. Severe cases often manifest with altered mental status or coma.</td>
<td>Serum glucose Electrolytes Urine ketones VBGs</td>
<td>DKA may be the first manifestation of diabetes in some patients. These patients often do not recognize the importance of polydipsia and polyuria. They often report only nausea, vomiting, and epigastric pain.</td>
</tr>
<tr>
<td>Pancreatitis</td>
<td>Acute</td>
<td>Presenting symptom is epigastric pain, which often radiates to the back. Most cases are caused by gallstones or alcoholism.</td>
<td>Common</td>
<td>Epigastric tenderness is present. Associated paralytic ileus may cause abdominal distention and decreased bowel sounds. Frank shock may be present in severe cases.</td>
<td>Lipase WBCs Serum glucose LDH AST Hematocrit BUN Calcium VBGs</td>
<td>Criteria correlating with higher mortality: At admission—age &gt;55 years old; WBCs &gt;16,000/mm³, glucose &gt;200 dl, base deficit &gt;4, LDH &gt;350 IU/L, AST &gt;250 IU/L. Within 48 hours—Hct drop of 10%, BUN &gt;2 mg/dl, Po₂ 4 L</td>
</tr>
<tr>
<td>Appendicitis</td>
<td>Acute</td>
<td>Abdominal pain classically begins in periumbilical region and later moves to right lower quadrant. Anorexia is common.</td>
<td>Common</td>
<td>Localized tenderness over right lower quadrant. Low-grade fever may be present.</td>
<td>WBCs Ultrasound Abdominal CT</td>
<td>Early appendicitis can be a difficult diagnosis to make. It is still frequently missed on the first physician encounter.</td>
</tr>
<tr>
<td>Bowel obstruction</td>
<td>Acute</td>
<td>Classically, abdominal pain consists of intermittent cramps occurring at regular intervals. The frequency of the cramps varies with the level of the obstruction; the higher the level, the more frequent the cramps. The location of the pain also varies with the level of the obstruction; high obstruction causes epigastric pain, midlevel obstruction causes periumbilical pain, colonic obstruction causes hypogastric pain.</td>
<td>Common</td>
<td>Abdominal distention, mild diffuse tenderness, and high-pitched “tinkling” bowel sounds may be present. Thorough search for hernias should be performed.</td>
<td>Electrolytes Lactate Abdominal ultrasound Abdominal CT</td>
<td>Adhesions, hernias, and tumors account for 90% of bowel obstructions. Other causes include intussusception, volvulus, foreign bodies, gallstone ileus, inflammatory bowel disease, stricture, cystic fibrosis, and hematoma.</td>
</tr>
<tr>
<td>Carbon monoxide (CO) poisoning</td>
<td>Acute</td>
<td>Headache is usually present. CO poisoning often occurs during winter months when furnaces are turned on. Family members may have similar symptoms if they also have been exposed.</td>
<td>Uncommon</td>
<td>No reliable signs of early CO poisoning</td>
<td>CO level</td>
<td>Because CO is a tasteless, odorless gas, patients may not realize they have been exposed. It is important to keep a high index of suspicion during the cold months.</td>
</tr>
<tr>
<td>Boerhaave's syndrome</td>
<td>Acute</td>
<td>Patients may have neck, chest, or epigastric pain. Forceful, protracted vomiting usually causes the tear. Most cases follow a bout of heavy eating and drinking. Other reported causes include childbirth, defecation, seizures, and heavy lifting.</td>
<td>Uncommon</td>
<td>Tachypnea, tachycardia, and hypotension may be present. Escaped air from the esophagus may produce subcutaneous emphysema. Air in the mediastinum produces a “crunching” sound as the heart beats (Hamman’s sign).</td>
<td>CXR may show pleural effusion, widened mediastinum, pneumothorax, or pneumomediastinum. Esophagogram with water-soluble contrast is definitive.</td>
<td>The classic presentation includes forceful vomiting, severe chest pain, subcutaneous emphysema, and multiple CXR findings. There is a growing body of evidence that most cases do not have this “classic” picture. In more subtle presentations, the diagnosis can be difficult to make.</td>

will have neuroimaging performed, and patients with suspected myocardial infarction will have an electrocardiogram (ECG) and cardiac enzyme testing. If an emergent cause of nausea and vomiting is confirmed or highly suspected based on the initial evaluation and ancillary testing, then appropriate management is undertaken. Patients who are generally well and have a low likelihood of a serious cause, whose symptoms are controllable, but for whom the diagnosis is still unclear, should have follow-up arranged within 24 to 48 hours for reevaluation if symptoms persist or more urgently if symptoms worsen or a new, concerning symptom, such as blood in the stool or vomit, fever, or localized pain, develops. Patients who have a suspected or confirmed nonemergent diagnosis are treated with antiemetic medications, with specific
management directed at the underlying cause. Patients with cyclical or recurrent vomiting syndromes do not require any particular diagnostic testing in the ED and should be managed in consultation with the patient's primary care physician. However, care should be taken to avoid anchoring on the patient’s previous diagnosis of cyclical vomiting syndrome and should seek corroborative information from the patient, the medical record, family members, or the primary physician to ensure that the pattern of the presentation fits the patient’s syndrome and to exclude alternate emergent causes of vomiting.

EMPERICAL MANAGEMENT

Symptomatic relief of nausea, vomiting, or pain should not await identification of the underlying cause. Decreased oral intake with concomitant fluid loss (by vomiting) causes dehydration. If the patient is mildly or moderately dehydrated and is able to take oral liquids, a solution containing sodium, carbohydrate, and water is recommended. Many sports drinks contain the proper balance of these elements. Patients who are severely dehydrated or in whom intake of oral fluids is not possible or is contraindicated should be given IV crystalloid solution (usually normal saline) and electrolyte abnormalities corrected. Placement of a nasogastric tube is not indicated, except in patients with bowel obstruction.

The need for antiemetics and the response to therapy may be measured with scales similar to those used for pain assessment, such as the visual analog scale and the verbal categorical scale.

Patients presenting to the ED with nausea or vomiting may have a known etiology with specific treatment aimed toward treating the underlying cause. These are discussed in the Specific Situations section.

For the patient with either non-obstructive GI causes or undifferentiated nausea and vomiting, there is very limited evidence to support one agent over another. A large, randomized trial of ED patients with undifferentiated nausea and vomiting found no difference in the primary outcome of reduction of symptoms between metoclopramide 20 mg IV, ondansetron 4 mg IV, or saline placebo. There was a decreased need for rescue antiemetics in patients who received metoclopramide; however, these patients also had more side effects. These findings were similar to previous smaller trials, where various commonly used medications were compared and no statistically significant difference between the various medications were found. Children, pregnant patients, and hemodynamically unstable patients were excluded from all studies. When comparing the raw data of all the randomized controlled trials, decreased nausea scores were associated with increasing amount of IV saline given. Although this has not been formally studied, IV fluids alone may be an effective treatment for nausea and vomiting.

The pharmacologic management of patients with nausea and vomiting is outlined in Table 26.5, and a management algorithm is shown in Figure 26.4. To allow the physician to tailor the appropriate choice for each patient, the pharmacologic therapies available may be classified into serotonin antagonists, histamine antagonists, muscarinic antagonists, and dopamine antagonists. The serotonin antagonists, particularly ondansetron, are considered first line therapies for most cases of nausea and vomiting in the ED, except in specific situations discussed later. Other

CNS, Central nervous system; CPA, cerebellopontine angle; HEENT, head, eyes, ears, nose, throat; ICP, intracranial pressure.
Vital signs, primary survey, basic history

Unstable or catastrophic cause likely

- Neurological deficits or comatose
  - Consider ICH, posterior CVA, meningitis, drug ingestion
    - Airway protection CT head; consider LP if CT head normal

- Severe abdominal pain or tenderness
  - Consider raptured viscus, mesenteric ischemia, ectopic pregnancy, SBO, DKA
    - Fingerstick glucose electrolytes, pregnancy test, lactate, emergent early surgical consultation

- Chest pain or SOB
  - Consider MI or Boerhaave’s
    - ECG troponins portable CXR

Stable

- Obtain comprehensive history and physical

- Chronic
  - History of regurgitating stomach contents
    - Consider imaging for gastric outlet obstruction

- Acute (see Fig 26.3B)
  - Consider CVS or CHS electrolytes consultation with PCP

Fig. 26.3. A and B. Approach to the patient with nausea and vomiting. Continued
Fig. 26.3., cont’d
serotonin antagonists (such as, granisetron) are available but have not been studied in the ED and therefore cannot be recommended over ondansetron. The initial dose of ondansetron is 4 to 8 mg IV. A single dose of up to 16 mg is considered safe in the non-elderly population. In the elderly, it is recommended that the initial dose should not exceed 8 mg infused over at least 15 minutes. Ondansetron at higher doses and faster infusion rates may cause QT prolongation in older patients. For most patients, there are few or no side effects of the serotonin receptor antagonists and, if they occur, are mild. If the patient is known to have a long QT or is at risk of developing long QT syndrome, then it is best to reserve ondansetron as a second line agent. Ondansetron has also been associated with serotonin toxicity when given concurrently with other serotonergic agents.

Metoclopramide (Reglan) is the other first line agent for use in the ED. Metoclopramide is an excellent general-purpose antiemetic. As a prokinetic agent, it is useful in patients with gastroparesis and other dysmotility syndromes. The initial dose of metoclopramide is 10 to 20 mg IV/intramuscular (IM).

The phenothiazines, prochlorperazine (Compazine) and promethazine (Phenergan), have historically been first-line agents in the ED due to the black box warning on QT prolongation. An ECG should be performed prior to administration to check for QT prolongation. A dose of 1.25 mg IV is sufficient in most patients. The dose may be repeated in 60 minutes if needed.

For patients with undifferentiated nausea and vomiting or those without specific causes listed in the special situations below, start with ondansetron 4 mg IV. It is inexpensive and generally well tolerated. IV crystalloid should also be given if there are no contraindications. A repeat 4 mg IV dose should be given initially if there is no response. If there is still an inadequate response, than metoclopramide 10 mg IV should be given, with a repeat dose of metoclopramide after 30 minutes, if needed.

If ondansetron and metoclopramide have not been effective and a mechanical obstruction is unlikely, consider using droperidol in a patient at low risk of adverse effects from the droperidol. Begin with 1.25 mg IV, and the dose may be repeated if no effect is seen within 30 minutes. If droperidol is not considered safe, then the next drug of choice should be prochlorperazine. A single dose of 10 mg IV is appropriate. If sedation is desired, promethazine may be given prior to trying prochlorperazine. For most patients, begin with promethazine 12.5 mg IV, which may be repeated in 30 minutes if tolerated. In patients who may not tolerate sedation, such as elderly patients, those with underlying respiratory diseases, or those with other sedating medications, begin at 6.25 mg IV, which may be incrementally increased as tolerated.
Fig. 26.4. Management algorithm for the patient with nausea and vomiting. CHS, cannabinoid hyperemesis syndrome; CVS, cyclical vomiting syndrome; IV, intravenous; NVP, nausea and vomiting of pregnancy; PO, per os (by mouth).
Headache

Patients with nausea or vomiting associated with a headache should be given metoclopramide as the first line agent. Metoclopramide will treat the both the headache, as well as the nausea and vomiting. Ondansetron may cause headache and therefore is not appropriate as a first line agent. If metoclopramide is ineffective, then prochlorperazine may be used a second line agent, because it has also shown to be effective in the treatment of headaches. Finally, droperidol is effective for headaches and for nausea and vomiting and should be considered if the first two agents fail.

Pregnancy

Many agents, both pharmacologic and non-pharmacologic have been evaluated in the treatment of nausea and vomiting of pregnancy and hyperemesis gravidarum. A recent Cochrane review concluded that there was insufficient high quality evidence to recommend one agent over another. Agents that have shown to be more effective when compared to placebo include ginger, vitamin B6 (pyridoxine), vitamin B6 combination products (such as, doxylamine with pyridoxine), ondansetron, and metoclopramide. Studies comparing ondansetron to metoclopramide have not shown a difference in effectiveness. Although the quality of the evidence is poor, there may be an association between ondansetron use and fetal malformations in the first trimester.

In pregnant patients presenting with nausea and vomiting, metoclopramide 10 mg IV should be the first line agent. Ondansetron should be reserved as a second line agent. If the pregnant patient is discharged from the ED, then a vitamin B6 combination product should be prescribed if her symptoms return.

Chemotherapy

Chemotherapy-related nausea and vomiting may be seen in ED patients. The chemotherapy-induced nausea and vomiting may be acute (up to 24 hours) or delayed (after 24 hours). Ondansetron is the first line agent and should be given at repeated doses. Start with 4 mg IV and repeat every 30 minutes up to 16 mg IV. A single dose of dexamethasone 10 mg IV should be added if the vomiting is refractory to the ondansetron.

Cyclical Vomiting

Patients with cyclical vomiting syndrome may be difficult to manage. They should receive IV hydration and may require high doses of an antiemetic medication, although once again, none of which has been deemed superior to another. Benzodiazepines are recommended in this condition, because inducing sleep often terminates the episode, especially if antiemetic therapy fails to abort the episode and admission is considered.

Although the evidence is primarily anecdotal, patients with cannabis hyperemesis syndrome should be treated with IV fluids, an antiemetic medication, and frequent hot showers. Patients should be advised to abstain from marijuana use, because that is the only known cure. Patients with a history of cannabis hyperemesis syndrome have been shown to relapse if they resume marijuana use, even after a long period of abstinence.

Vertigo

Antihistamines are useful in nausea and vomiting associated with motion sickness and vertigo. Agents such as dimenhydrinate (Gravol, Dramamine) and meclizine (Antivert) directly inhibit vestibular stimulation and vestibular-cerebellar pathways. Their anticholinergic effect also may contribute to their effectiveness in vertigo and motion sickness. Antihistamines have some role as general antiemetics but are better used in the prevention of motion sickness. The most common side effects of antihistamines are drowsiness, blurred vision, dry mouth, and hypotension.

DISPOSITION

Hospital admission is appropriate when the patient has a significant underlying disease, has an unclear diagnosis and responds poorly to fluid and antiemetic therapy, continues to experience uncontrolled emesis refractory to medication, or is at the extremes of age with poor response to treatment. More difficult disposition decisions are related to patients in whom the diagnosis is unclear and prospects for timely follow-up are poor. Discharge may be considered if no serious underlying illness is present, the response to fluid and antiemetic therapy is good, the patient is able to take clear liquids before discharge, and the prospects for follow-up and observation at home are favorable.

Close follow-up often is advisable for discharged patients, preferably with their primary care physician, in 24 to 48 hours. At discharge, the patient is prescribed medications as needed and is advised to restart oral intake with small feedings of a liquid diet with gradual return to a normal diet. Clear instructions are given to return to the ED if there is a recurrence, change, or deterioration in symptoms.

Causes for nausea and vomiting frequently remain undiagnosed. Some cases declare themselves or resolve over time; reevaluation and close follow-up are fundamental in the care for patients with continuing symptoms.

KEY CONCEPTS

- Nausea and vomiting can result from a primary problem in the GI tract but can also be secondary to problems in the neurological, vestibular, urogenital, and cardiac systems.
- Associated symptoms and a medication/drug history are the most helpful in narrowing the differential diagnosis in the acutely vomiting patient.
- Laboratory studies are not required in all patients who vomit. Patients with severe or protracted vomiting, sufficient to require IV rehydration, should have their electrolytes and renal function determined and corrected.
- In a patient with undifferentiated nausea or vomiting or vomiting due to non-obstructive GI disease, ondansetron is the first line antiemetic.
- Although evidence is limited, metoclopramide is the antiemetic of choice in hyperemesis gravidarum and vomiting associated with headache; ondansetron is the drug of choice in chemotherapy induced vomiting.
- Antiemetics should not be prescribed routinely in patients receiving opioid analgesia.

CHAPTER 26: QUESTIONS & ANSWERS

26.1. Which of the following metabolic derangements is most likely in a patient with severe, protracted vomiting?  
A. Hypochloremic, hypokalemic, metabolic alkalosis  
B. Hypochloremic, hypokalemic, metabolic acidosis  
C. Hyperchloremic, hypokalemic, metabolic alkalosis  
D. Hyperchloremic, hypokalemic, metabolic acidosis  
E. Hyperchloremic, hyperkalemic, metabolic acidosis  

Answer: E. Severe, protracted vomiting can cause a hypochloremic, hypokalemic, metabolic alkalosis. The metabolic alkalosis is produced by loss of hydrogen ions in the vomitus. Many factors serve to maintain the alkalosis including volume contractions, hypokalemia, chloride depletion, shift of extracellular hydrogen ions into cells, and increased aldosterone. Hypokalemia is produced primarily by loss of potassium in the urine. The metabolic alkalosis leads to large amounts of sodium bicarbonate being delivered to the distal tubule. Secondary hyperaldosteronism from volume depletion causes reabsorption of sodium and excretion of large amounts of potassium in the urine.

26.2. Antihistamines would most effectively control the nausea and vomiting caused by which of the following conditions?  
A. Chemotherapy administration  
B. Digoxin ingestion  
C. Gastritis  
D. Gastroparesis  
E. Labyrinthitis  

Answer: E. Antihistamines are useful in nausea and vomiting associated with labyrinthitis, motion sickness, and vestibular disorders by directly inhibiting vestibular stimulation and vestibulocerebellar pathways. Their anticholinergic effect may also contribute to their effectiveness in vertigo and motion sickness.

26.3. A 35-year-old man is given 10 mg of IV prochlorperazine for treatment of nausea. Fifteen minutes after the administration of medication, he displays protrusion of his tongue, difficulty speaking, intermittent contractions of his facial muscles, and anxiety. Which of the following would be the most appropriate next step in the management of this patient?  
A. Administer benztrapine mesylate  
B. Administer haloperidol  
C. Five-point physical restraints  
D. Rapid sequence intubation  
E. Repeat dose of prochlorperazine  

Answer: A. The described patient is experiencing a dystonic reaction to prochlorperazine (Compazine). Drug-induced dystonic reactions most commonly occur with antipsychotic, antidepressant, and antiemetic medications. Administration of an anticholinergic medication such as benztrapine mesylate (Cogentin) or diphenhydramine (Benadryl) is the treatment of choice and typically aborts the reaction. Benzodiazepine administration may occasionally be necessary if the previously mentioned medications are ineffective. Artificial airway placement and use of restraints are rarely required. Further dopamine receptor blockade with haloperidol or additional doses of the offending agent would not prove useful.

26.4. Where is the principal site of action of the serotonin receptor antagonist ondansetron?  
A. Area postrema  
B. Basal ganglia  
C. GI tract  
D. Hypothalamus  
E. Vestibular system  

Answer: A. The serotonin receptor antagonists such as ondansetron, granisetron, and tropisetron are a class of agents that have generated much interest secondary to their effect on chemotherapy-induced emesis. Their principal site of action is the area postrema, which is located in the lateral reticular formation of the medulla. They also exert some effect on receptors of the GI tract; however, this is secondary to their effect in the area postrema.

26.5. What is the most common cause of nausea and vomiting in the adult population?  
A. Acute gastroenteritis  
B. Drug side effects  
C. Febrile systemic illness  
D. Motion sickness  
E. Pregnancy  

Answer: B. In adult medicine, nausea and vomiting are caused most often by medications. When considering the entire population (pediatrics and adults), the three most common causes of nausea and vomiting are acute gastroenteritis, febrile systemic illnesses, and drug effects.
CHAPTER 27

Gastrointestinal Bleeding

David A. Meguerdichian | Eric Goralnick

PERSPECTIVE

Upper and lower gastrointestinal bleeding (GIB) are defined based on their location relative to the ligament of Treitz in the terminal duodenum, so esophagus, stomach, and duodenum origin bleeds are upper and all others are lower. Upper GIB (UGIB) mortality rates have remained constant at about 15% over the past 2 decades despite advances in medical therapy, intensive care unit (ICU) management, endoscopy, and surgery. This is most likely due to the increasing proportion of older patients, who may die due to comorbid conditions, and increases in cirrhotic and variceal patients. The lower GIB (LGIB) mortality rate is approximately 4%. Predictors include age older than 70 years, intestinal ischemia, comorbid illness, coagulation defects, transfusion of packed red blood cells, and male gender.

DIAGNOSTIC APPROACH

Differential Considerations

The characteristics of the GIB, age of the patient, and social factors can all help determine the cause. UGIB can routinely manifest as bloody or coffee-ground–like vomit termed hematemesis or as dark, tarry stools termed melena. In older adults, peptic ulcer disease, esophagitis, and gastritis account for most cases. Younger patients typically present with Mallory-Weiss tears, GI varices, and gastropathy (Table 27.1). As a whole, peptic ulcer disease makes up more than 50% of all acute cases of UGIB seen in the emergency department (ED). 1 In pediatric patients, gastric and duodenal ulcers, esophagitis, gastritis, esophageal varices, and Mallory-Weiss tears account for most cases of UGIB, in descending order of frequency. LGIB usually produces bright red or maroon blood per rectum, termed hematochezia. LGIB may be classified according to pathophysiologic cause—inflammatory, vascular, oncologic, traumatic, or iatrogenic. Anorectal sources, such as hemorrhoids, are the most common causes of LGIB in all age groups. In adults, the most common sources of hematochezia are colonic diverticula and angiodysplasia. Other noteworthy causes include colitis caused by ischemia, infection, and inflammatory bowel disease. Among older patients with cardiovascular disease, ischemic colitis as a cause for LGIB has been increasing. Although uncommon, a brisk UGIB may present as hematochezia and be mistaken for a bleed from a lower GI source. Up to 14% of bleeds characterized as hematochezia are due to such lesions and are associated with higher transfusion rates, surgical interventions, and mortality. Major causes of LGIB in children include anorectal fissures and infectious colitis. Bleeding can also be caused by intussusception and Meckel’s diverticulum in infants and toddlers. Despite diagnostic advances for all ages, the source of GIB is not identified in nearly 15% of patients. Death from exsanguination resulting from GIB is rare. However, there are two causes of GIB that may rapidly cause death if not recognized and mitigated, esophageal varices and aortoenteric fistula. The former, which typically arises from portal hypertension usually caused by alcoholic cirrhosis, is the single most common source of massive UGIB and has a mortality rate of 30%. The latter is caused when an abdominal aortic aneurysm or, more commonly, an aortic graft adheres to and erodes through a bowel wall. Aortoenteric fistula is a rare but rapidly fatal cause of GIB, with the mortality of an untreated fistula of nearly 100%. Aortoenteric fistula is a primary consideration in patients with GIB and known abdominal aortic aneurysms or aortic grafts until an alternative bleeding source is identified. Prompt surgical consultation is warranted when aortoenteric fistula is a likely diagnosis.

Finally, in the differential considerations, one must determine whether the blood is actually of GI origin. Epistaxis, dental bleeding, or red food coloring can mimic the appearance of hematemesis. Bismuth-containing medications and iron supplements can create melanotic-appearing (but guaiac-negative) stools. Vaginal bleeding, gross hematuria, and red foods (eg, beets) can all be mistaken for hematochezia (Box 27.1). Unless an alternative diagnosis is clearly evident, the appropriate approach is to continue with the evaluation for GIB.

Pivotal Findings

The history centers on the GI tract and on the timing, quantity, and appearance of the bleeding. Relevant comorbid conditions should be reviewed as well (Box 27.2). The extent of the history will be dictated by the severity of the complaint and hemodynamic stability of the patient on ED arrival. Reviewing the patient’s vital signs, appearance of the stool, and basic laboratory studies will help identify the bleeding source and guide treatment.

Symptoms

A useful starting point for the emergency clinician is to determine the time of onset, duration of symptoms, and relevant supporting historical facts. Often, the degree of bleeding is better gauged by assessing symptoms associated with significant intravascular loss, such as weakness, shortness of breath, angina, orthostatic dizziness, confusion, palpitations, and report of cool extremities. Blood loss more than 800 mL will usually result in the onset of these complaints, with severe symptoms being described at a threshold greater than 1500 mL. Such symptoms indicate a decreased oxygen-carrying capacity that often accompanies significant blood loss and should prompt a thorough and expeditious evaluation and resuscitation. The context of the bleeding can help explain its cause. For example, if a patient complains of bright red blood per rectum after several days of constipation and straining, that presentation suggests an anorectal source. Alternatively, a patient with hematemesis after several earlier episodes of retching would lead one to suspect an esophageal tear. Finally, a patient with easy bruising and recurrent gingival bleeding might suggest an underlying coagulopathy.

Efforts should be made to quantify the amount of blood lost during the bleeding event. Patients may describe the passage of large clots, blood changing the toilet bowl water red, or simply streaks of blood on the toilet paper. The patient’s recollection of

Alternative Diagnoses or Mimics of Gastrointestinal Bleeding

- Melena
  - Ingestion of bismuth medications
  - Ingestion of activated charcoal

- Hematemesis
  - Nasopharyngeal bleeding (eg, nosebleeds, dental bleeding)
  - Ingestion of red drinks or food

- Hematochezia
  - Vaginal bleeding
  - Gross hematuria
  - Partially digested red food (eg, red beets, red grapes)

Characteristics of Patients With High-Risk Gastrointestinal Bleeds

- Medication use
  - Aspirin
  - Nonsteroidal antiinflammatory drugs
  - Steroids
  - Anticoagulants (warfarin, heparin)
  - Chemotherapeutic agents
- History of peptic ulcer disease
- Known liver disease, cirrhosis
- Advanced age (>60 yr)
- Alcoholism
- Current smoker
- Chronic medical comorbidities
  - Congestive heart failure
  - Diabetes
  - Chronic renal failure
  - Malignancy
  - Coronary artery disease
- History of abdominal aortic aneurysm graft

Key Historical Information for Patients With Gastrointestinal Bleeds (GIBs)

- Events prior to or leading up to the bleeding episode
- Severity, frequency, and quantity of the bleeding episode
- Appearance and color of the bleed
- Medical history, including risk factors for GIB:
  - Prior bleeding episodes and any identified source
  - Medication use that may increase the risk of GIB
  - Social factors that may increase the risk of GIB
  - Symptoms patient is experiencing with the bleeding episode

A review of the patient’s relevant medical history and risk factors for bleeding should note whether a patient has had similar bleeding before and the location of the causative lesion (Box 27.3). This is especially important with UGIB because most of these presentations are caused by rebleeding of previously identified sources. Next, identification of relevant comorbid diseases helps risk-stratify these patients in the context of their bleed. Patients with GIB and a history of coronary artery disease, congestive heart failure, liver disease, or diabetes have a higher mortality and therefore may require earlier or more extensive interventions.

A review of the patient’s medications should pay particular attention to gastrotoxic substances, anticoagulants, and antiplatelet drugs. Medications such as nonsteroidal antiinflammatory drugs (NSAIDs), aspirin, warfarin, clopidogrel, corticosteroids, and certain chemotherapeutic agents are known to increase the risk of GIB by as much as threefold. In addition, reviewing the patient’s social history can identify activities that increase risk for GIB. Alcohol abuse is associated with gastritis and peptic ulcer disease. It can also result in cirrhosis, portal hypertension and, ultimately, esophageal variceal bleeding. Smoking cigarettes results in slower healing and greater recurrence of ulcers. These two social habits are also closely associated with GI malignancy—another, albeit rare, risk factor for GIB.

Signs

Hypotension and tachycardia can suggest moderate hypovolemia and can be the early indicators of impending shock. Normal vital signs do not preclude the possibility of a severe bleed. Orthostatic vital signs, although frequently used historically, are insufficiently sensitive or specific to be of value in determining volume status in the context of acute blood loss.
Mental status is evaluated for signs of poor cerebral perfusion. Generalized pallor in a hemodynamically stable patient might indicate the anemia of a subacute or chronic GIB; in the unstable patient, pallor might reinforce the impression of malperfusion caused by massive blood loss. Cold clammy skin on the extremities signal significant volume loss consistent with hemorrhagic shock. Ecchymoses or petechiae suggest a coagulopathy. Finally, jaundice, palmar erythema, or spider angiomas suggests the possibility of UGIB from esophageal varices.

The abdomen is carefully examined for subtle findings that can help identify the source of bleeding. Hyperactive bowel sounds are a nonspecific finding, but might indicate UGIB, because intraluminal blood is a known cathartic that can stimulate peristalsis. Tenderness to palpation can be seen in many cases of peptic ulcer disease. Severe diffuse tenderness on examination warrants the consideration of bowel ischemia, mechanical obstruction, ileus, or bowel perforation. Evidence of peritonitis merits a rapid surgical consultation for possible operative management. The abdominal examination may also show further signs of portal hypertension with the presence of hepatomegaly, ascites, or caput medusae. The rectal examination helps determine the type of bleeding and should be performed in most patients with GIB. The examination should include evaluation of the external anus, digital rectal examination and, when local bleeding is thought to be the cause, anoscopy for hemorrhoids, polyps, or fissures.

Ancillary Testing

Occult Blood and Guaiac Bedside Testing

In patients with suspected UGIB, guaiac testing can be performed at the bedside to evaluate for occult blood, even when stool appears normal. The test makes use of the pseudoperoxidase activity found in hemoglobin. When hydrogen peroxide is dripped onto the guaiac paper containing the stool sample, an oxidative reaction rapidly turns the paper blue. The test can actually be positive for up to 2 weeks after an acute bleed and thus is more useful for diagnosing chronic occult bleed. Uncommonly, false-positive results can be triggered by ingestions of red meat, turnips, horseradish, vitamin C, methylene blue, and bromide preparations. Iron- and bismuth-containing medications can cause dark stools that will be guaiac-negative. Similar testing is available for gastric contents but testing of UGI aspirates and vomitus is less reliable than testing of an LGI sample, and we do not recommend it. The clinical impression of an UGIB should override any testing. The diagnostic and prognostic limitations of nasogastric (NG) tube insertion are discussed below.

Laboratory Studies

Laboratory studies can assist in the risk stratification of GIB. Minimum testing should include evaluation of the patient’s hemoglobin and blood urea nitrogen (BUN) levels, coagulation studies, and platelets. The hemoglobin level does not immediately decline in the setting of an acute bleed, because whole blood is lost. Changes in hemoglobin levels are typically seen after 24 hours, when there is hemodilution from shifting extracellular fluids and intravenous (IV) hydration with crystalloid. Nevertheless, acute hemoglobin levels less than 10 g/dL have been positively correlated with higher rates of rebleeding and mortality. Blood transfusion is indicated in a patient with GIB when their hemoglobin level is acutely less than 7 to 8 g/dL, they are experiencing vigorous blood loss, or they require further resuscitation beyond 2 L of crystalloid due to unstable vital signs. An even lower threshold for transfusion is indicated in older adults and those with significant comorbidities, such as coronary artery disease. Absorption of digested blood breakdown products into the circulatory system from the gut causes elevation of BUN levels. The BUN level can also be elevated from prerenal azotemia in the setting of hypovolemia. A BUN-to-creatinine ratio greater than 36 when the patient does not have renal failure has a sensitivity of 90% in predicting GIB, but specificity is very low, at 27%. Coagulation studies, particularly prothrombin time, monitor for coagulopathy in the context of blood loss and replacement. This becomes especially important in patients with liver disease or those taking therapeutic anticoagulants such as warfarin.

Other laboratory tests rarely are useful in patients with GIB. Electrolyte abnormalities may be present in patients with repeated or prolonged episodes of vomiting or diarrhea. Leukocytosis often is present because of the stress response to acute blood loss and should not be considered to represent underlying infection unless other indications of infection are present. The serum lactate level is elevated when circulatory shock is present or, much less commonly, from gut ischemia, if that is the cause of the GI blood loss.

Blood is sent to the blood bank for a type and screen if the patient is stable and for crossmatching if blood loss is brisk or the patient is hemodynamically unstable or has significant comorbidities, especially heart disease. If the patient is highly unstable, transfusion of non–crossmatched blood may be necessary.

Electrocardiography

Because GIB and its subsequent anemia can reduce the oxygen-carrying capacity of blood, patients should be screened for signs of myocardial ischemia. We recommend obtaining an electrocardiogram for all patients older than 40 years, those with any symptoms of ischemia, and those with known coronary artery disease who are at higher risk for ischemic events. Electrocardiographic findings consistent with myocardial ischemia likely represent demand ischemia rather than coronary thrombosis and are treated with restoration of adequate circulatory volume, including blood, if needed.

Imaging

Emergent imaging of the chest or abdomen in the ED setting is rarely indicated in the patient with acute GIB. When bowel perforation is suspected on the basis of peritoneal findings on examination, abdominal computed tomography (CT) is the imaging test of choice. Abdominal plain radiographs are of no value for patients with GIB, except in the rare case where bowel obstruction is strongly suspected. In the absence of clinical findings consistent with perforation or bowel ischemia, CT of the solid abdominal organs is not indicated and does not alter the acute management and disposition of the patient with a GIB.

When endoscopy is not possible or cannot locate the hemorrhage source, CT angiography (CTA) is the principle diagnostic imaging tool and has the benefit of allowing for therapeutic options via embolization. CTA has a sensitivity of 85% and specificity of 92% for detecting acute GIB. Conventional angiography is indicated in a very small proportion of cases of GIB and requires a hemorrhage rate of greater than 0.5 mL/min to detect the bleed. Although also potentially therapeutic, angiography has a high complication rate, including acute renal failure, contrast reactions, and bowel infarction. Angiography has a sensitivity of 46% and specificity of 100% for acute bleeds (Fig. 27.1).

Tagged red blood cell imaging or nuclear scintigraphy involves erythrocyte injection to detect indolent or elusive bleeding and is primarily useful in the inpatient setting. Scanning must be performed within 2 hours of injection to localize bleeding accurately (Fig. 27.2).
With numerous approaches available, the American College of Radiology has developed an appropriateness rating scale to help guide emergency clinicians in the use of specific interventions and imaging modalities for patients presenting with GIB (Table 27.2).

### DIAGNOSTIC ALGORITHM

The diagnostic approach to the GIB patient involves a number of key decision points. First, the emergency clinician should assess the patient’s general appearance, vital signs, and volume status. This initial assessment can help categorize the patient as stable or unstable. If the patient is unstable, resuscitation begins with the immediate placement of two large-bore IV catheters (18 gauge or larger) or central venous catheter placement and crystalloid infusion, with the aim of establishing and maintaining adequate tissue perfusion. This does not equate to restoration of normal blood pressure, however, and maintaining a systolic blood pressure in the range of 100 mmHg is a good initial resuscitative goal. End points of adequate resuscitation would include evidence of adequate perfusion of skin, urine output greater than 1 mL/kg/hr, and normal mental status.

The second decision point involves use of the history and physical examination findings to determine if the patient has UGIB or LGIB. These details will help risk-stratify the GIB patient further and establish the differential diagnosis. Once the presumptive origin of the bleed has been determined, the emergency clinician should consider the anticipated hospital course of the patient.

**NOTE:** Rating scale from 1 to 9, with 1 = least appropriate and 9 = most appropriate.

The third decision point relies on the severity of the UGIB or LGIB to determine the ED management and disposition.

A later section of this chapter (see “Disposition”) discusses risk stratification and hospitalization recommendations. In general, patients who are young, reliable, and hemodynamically stable, with a clear source of bleeding (eg, a minor bleed in a clear context of a Mallory-Weiss tear), can be discharged after an observation period of 12 hours in the ED or ED observation unit. The patient who has been properly resuscitated in the ED and remains hemodynamically stable will require urgent GI consultation, so admission to a medical inpatient unit or observation unit for further evaluation and management is indicated. LGIB patients who are hemodynamically stable, are reliable, have no significant risk factors, and have a clearly visualized source of bleeding on
examination can be safely discharged to follow-up with their outpatient provider.

Unstable UGIB will require emergent gastroenterology consultation, consideration of intubation if shock or hemorrhage is severe, and admission to an ICU for continued resuscitation and emergent endoscopy. Unstable LGIB patients require emergent surgical consultation. Management initially centers on proper resuscitation with fluids, blood products, and admission to the ICU.

**MANAGEMENT**

**Empirical Treatment**

Rapid identification of the bleeding source (ie, upper vs. lower GI tract), risk stratification, resuscitation, consultation, and disposition are the integral elements of this process. Massive bleeding, active hematemesis, hypoxia, severe tachypnea, and/or altered mental status may mandate tracheal intubation for protection and to supplement tissue oxygenation. Fig. 27.3 presents a combined diagnostic and management algorithm.

**Resuscitation**

Hemodynamic instability and estimated volume loss should guide initial resuscitation efforts. Patients should be placed on pulse oximetry and should receive supplemental oxygen with prompt crystalloid resuscitation through two peripheral, large-bore IV catheters. Cardiac telemetry should be initiated because demand ischemia and myocardial infarction may occur in patients with significant GIB.

**Blood Product Transfusion**

Continued hemodynamic instability or ongoing hemorrhage dictate the need for blood transfusion. Factors such as age, comorbidities (eg, ischemic heart disease, peripheral vascular disease, heart failure), baseline hemoglobin and hematocrit levels, and evidence of cardiac, renal, or cerebral hypoperfusion should be considered when determining transfusion quantity. Blood transfusion is immediately indicated in patients with GIB who have a hemoglobin level acutely less than 7 to 8 g/dL, are experiencing vigorous blood loss, or require further resuscitation beyond 2 L of crystalloid to maintain a systolic blood pressure in the range of 100 mm Hg.

Coagulopathy, especially in patients with underlying liver disease or those requiring massive transfusions, should be corrected promptly. We recommend either a 1:1:1 or a 1:1:2 ratio of plasma to platelets to packed RBC.4

**Nasogastric Aspiration and Lavage**

NG tube placement with aspiration or gastric lavage is not indicated for the evaluation of GIB.5 Despite its long time role, with advocates citing diagnostic and prognostic value, evidence has confirmed that it is not useful for either of these purposes. The sensitivity of NG aspiration and lavage for predicting later recurrence or worsening of UGIB is low, and the negative likelihood ratio in patients with melena or hematochezia without hematemesis is poor.6 Up to 15% of patients without blood or coffee-ground material in NG aspirates have been found to have high risk lesions on endoscopy. NG tube placement is not a benign procedure and has been associated with complications, including pain, aspiration, pneumothorax, pharyngeal or esophageal perforation, and gastric lesions. Occasionally, a consulting gastroenterologist may wish to place an NG tube in hopes of improving endoscopic visibility (and accuracy) by evacuating gastric contents and blood but, absent such an indication, we do not recommend placement of an NG tube in patients with suspected UGIB.

**Sengstaken-Blakemore Tube**

A bedside balloon tamponade should only be considered in exsanguinating patients with likely variceal bleeding when endoscopy is not immediately available. Complications are common and significant, but tube placement is indicated in the appropriate patient population due to the high mortality of uncontrolled bleeding. Insertion of these tubes is a rarely performed procedure, and emergency clinicians have resorted to novel approaches, including indirect laryngoscopy with a GlideScope, to aid placement.7

**Pharmacologic Agents**

Several medications may improve GIB outcomes. Proton pump inhibitor (PPI) infusions have long been a staple of acute GIB therapy, but evidence has contradicted their necessity in the emergent setting. A recent systematic review has found no evidence to suggest that PPI therapy affects clinically important outcomes such as mortality, rebleeding, or subsequent surgery.8 However, the infusion of high-dose PPIs before endoscopy has been proven to accelerate the resolution of signs of bleeding in ulcers and reduce the need for endoscopic sclerotherapy and thermocoagulation. Therefore, we recommend initiating IV dosing of an 80-mg bolus of omeprazole, followed by 8 mg/hr by continuous IV infusion for 3 days. High-dose oral PPIs, such asesomeprazole, 40 mg bid, have been shown in Asian populations to reduce the risk of rebleeding, need for surgery, and risk of death, but additional data are needed to determine whether those findings are generalizable to Western patients. If oral therapy proves equivalent to IV therapy, oral PPI therapy would decrease cost, dosage, and supply shortfalls.9

Somatostatin and octreotide, synthetic analogues, are splanchnic vasoconstrictors that reduce portal hypertension and the risk of persistent bleeding, rebleeding, and transfusion requirements in patients with variceal bleeding. Octreotide should be empirically administered to patients presenting with an acute GIB and history of significant liver disease, variceal bleeding, or alcoholism or with abnormal liver function tests. Octreotide is given as a 50-μg bolus followed by 50 μg/hr continuous IV infusion. Octreotide is not indicated for presumed nonvariceal bleeding. Although an older meta-analysis purported to show benefit for patients with nonvariceal GIBs who were treated with somatostatin, the individual studies were poor, and there is insufficient evidence to support its use.

Vasopressin, administered by continuous IV infusion, also reduces splanchnic blood flow and portal hypertension. However, we do not recommend its use due to the risk of significant complications, including myocardial and mesenteric ischemia and infarction.

**Definitive Management**

**Consultation**

Patients with hemodynamic instability and severe bleeding of a presumed upper GI source should have emergent gastroenterology consultation. Severe LGIB warrants emergent surgical consultation.

**Endoscopy**

Upper endoscopy is the most effective diagnostic and therapeutic intervention for UGIB, achieving hemostasis in greater than 90% of cases. Endoscopic hemostasis decreases rates of rebleeding,
mortality, and urgent surgery. Endoscopic treatments include injection therapy (e.g., saline, vasoconstrictors, sclerosing agents, tissue adhesives, or a combination), thermal therapy with the use of contact methods, such as multipolar electrocoagulation and heater probe, or noncontact methods, such as argon plasma coagulation and mechanical therapy, principally endoscopic clips. Endoscopy within 13 hours of bleeding reduces mortality in high-risk patients.\(^6\)

**Colonoscopy**

Urgent colonoscopy has variable diagnostic value for the identification of a bleeding source in LGIB. Lesion visualization is maximized by bowel preparation with polyethylene glycol in brisk, but not severe, hemorrhage. Consultation with a surgeon or gastroenterologist guides decision making with regard to the need for urgent colonoscopy.

CHAPTER 27: QUESTIONS & ANSWERS

27.1. Which of the following cannot clinically mimic hematemesis?
A. Dental bleeding
B. Bismuth-containing medication
C. Oral trauma or injury
D. Red food coloring
E. Severe epistaxis

Answer: B. When evaluating a patient with an upper gastrointestinal (GI) bleed, one must consider other potential causes that are not related to the GI tract. Epistaxis, dental bleeding, oral trauma, and red food coloring can mimic the appearance of hematemesis. Bismuth-containing medication can create melanotic-appearing, guaiac-negative stools, so this presentation is not truly consistent with the findings of hematemesis and a possible upper GI bleed.

27.2. A 56-year-old man presents with nausea, vomiting, and hematemesis since early this morning. He reports vomiting a combination of coffee-ground emesis and, more recently, bright red blood. His past medical history is significant for heavy alcohol use and known esophageal varices. On arrival, he is pale and diaphoretic. His vitals are remarkable for a blood pressure of 90/54 mm Hg and a regular heart rate of 118 beats/min. What is the most appropriate initial step in management?
A. Consult a gastroenterologist for immediate endoscopy
B. Perform a rectal examination to confirm a gastrointestinal bleed
C. Perform electrocardiography to evaluate a cardiac cause for the patient's presentation
D. Perform emergent abdominal plain radiography to evaluate the cause of the GI bleed
E. Place two large-bore intravenous catheters and begin crystalloid resuscitation

Answer: E. If a patient with a reported GI bleed is unstable, the initial step in management involves resuscitation with the immediate placement of two large-bore intravenous catheters (18 gauge or larger) and crystalloid infusion. Other diagnostic measures, such as performing electrocardiography or imaging, can be carried out after the initial step of gaining venous access and initiating resuscitation. It is important to note that abdominal plain films are rarely helpful in patients with GI bleeding unless bowel obstruction is suspected. Gastroenterology consultation is an important part of this patient’s care plan; however, it is not the first step in management after the evaluation.

27.3. A 65-year-old man presents with weakness, fatigue, melena, and increasing amounts of coffee-ground emesis over the last 24 hours. The patient has a known history of cirrhosis and heavy alcohol abuse. On examination, he is pale and diaphoretic and has rectal findings showing a combination of melena and hematochezia. His vital signs show a blood pressure of 75/40 mm Hg and a regular heart rate of 125 beats/min. You place two large-bore intravenous (IV) catheters and attempt to resuscitate the patient with crystalloid, but the patient shows no improvement after 2 L of fluid. At this point, the management of this patient should include all of the following, except which one?
A. Emergent gastroenterology consultation for endoscopy
B. Emergent intensive care unit (ICU) consultation for admission, further evaluation, and monitoring
C. Placement of a nasogastric (NG) tube with gastric lavage
D. Transfusion of 1 unit of fresh frozen plasma (FFP) for every 4 units of packed red blood cells
E. Transfusion of packed red blood cells

Answer: C. Placement of an NG tube in suspected upper GI bleed is not recommended. The sensitivity of this modality for predicting upper GI bleed is low, and there is a negative likelihood ratio in patients with melena or hematochezia. Along with this, NG tube placement has been associated with severe complications, including aspiration, pneumothorax, perforation, and development of gastric lesions. Transfusion of packed red blood cells and FFP is indicated here because the patient is hemodynamically unstable and likely to be suffering from coagulopathy resulting from his liver disease. Both GI and ICU consultation should be pursued because the patient will require endoscopy and close monitoring.

27.4. Which of the following statements regarding the epidemiology of GI bleeding is correct?
A. LGIB affects a larger portion of patients than does UGIB.
B. LGIB requiring admission is more common in adults than in children.
C. Most deaths secondary to GI bleeding occur in patients older than 60 years.
D. Overall mortality has remained the same over the past 20 years.
E. UGIB is more common in women than in men.

Answer: C. The overall mortality of GI bleeding is approximately 13% to 14% and has not changed significantly since the 1960s. LGIB affects a smaller portion of patients and results in proportionally fewer hospital admissions than UGIB. GI bleeding can occur in individuals of any age but usually affects people in their

REFERENCES

40s through 70s (mean age, 59 years). Most deaths caused by GI bleeding occur in patients older than 60 years. UGIB is more common in men than in women (2:1), whereas LGIB is more common in women. Significant UGIB requiring admission is more common in adults, whereas LGIB requiring admission is more common in children.

27.5. What is the most common cause of significant upper GI bleeding in adults?
A. Duodenitis
B. Esophagitis
C. Gastric erosions
D. Peptic ulcer disease
E. Varices

Answer: D. The most common cause of significant upper GI bleeding in adults is peptic ulcer disease. In descending order of frequency, this is followed by gastric erosions, varices, Mallory-Weiss tear, esophagitis, and duodenitis.

27.6. What is the most common cause of significant lower GI bleeding in adults?
A. Cancer
B. Diverticular disease
C. Inflammatory bowel disease
D. Rectal disease
E. Upper GI bleeding

Answer: B. The most common cause of significant lower GI bleeding in adults is diverticular disease. In descending order of frequency, this is followed by angiodysplasia, upper GI bleeding, cancer or polyps, rectal disease, and inflammatory bowel disease.

27.7. What is the most common cause of upper GI bleeding in children?
A. Esophageal varices
B. Esophagitis
C. Gastric and duodenal ulcers
D. Gastritis
E. Mallory-Weiss tear

Answer: C. Gastric and duodenal ulcers are the most common cause of upper GI bleeding in children. In descending order of frequency, this is followed by esophagitis, gastritis, esophageal varices, and Mallory-Weiss tear.

27.8. What is the most common cause of lower GI bleeding in children?
A. Anorectal fissure
B. Infectious colitis
C. Inflammatory bowel disease
D. Intussusception
E. Polyps

Answer: A. Anorectal fissure is the most common cause of lower GI bleeding in children. In descending order of frequency, this is followed by infectious colitis, inflammatory bowel disease, polyps, intussusception, and Meckel's diverticulum.

27.9. Which of the following has been shown to decrease rebleeding occurrences effectively in patients treated for upper GI bleeding secondary to esophageal varices?
A. Cimetidine
B. Famotidine
C. Octreotide
D. Omeprazole
E. Vasopressin

Answer: C. Octreotide is a useful addition to endoscopic sclerotherapy and decreases rebleeding occurrences. Patients with documented esophageal varices and acute upper GI bleeding should be treated with an intravenous infusion of DAM, 50 µg/hr, for a minimum of 24 hours while being observed in the intensive care unit.

27.10. Emergent surgical consultation should be obtained in a patient with GI bleeding and which of the following?
A. Esophageal varices
B. History of abdominal aortic graft
C. Initial systolic blood pressure < 100 mm Hg
D. Liver disease
E. Transfusion requiring 4 units of blood

Answer: B. Emergent surgical consultation is needed for patients who have abdominal aortic grafts and who present to the emergency department with GI bleeding because of the possibility of an aortoenteric fistula. Consultation with a surgeon should be obtained if it appears that more than 5 units of blood is required to achieve hemodynamic stability or if there is reasonable suspicion that operative intervention may be needed. This is especially true for patients older than 65 years. Patients with a history of varices, persistent postural changes in heart rate, or significant bright red blood per rectum are more likely to require surgery than patients without these findings.
Diarrhea is a clinical symptom of numerous infectious and noninfectious diseases. It encompasses mild presentations requiring supportive treatment to that of severe dehydration resulting in septic shock or even death. New challenges emerge as immunosuppression, global traveling, and comorbid conditions affect the assessment and management of patients. The evaluation requires a systemic approach that narrows diagnostic considerations and directs testing and management.

**Epidemiology**

Despite advances in care, diarrhea continues to be a major global health concern. According to the World Health Organization (WHO), there are over 1.7 billion cases of diarrhea every year; it is responsible for 760,000 deaths in children annually. In the United States, there are 179 million cases of acute diarrheal illness each year resulting in over 900,000 hospitalizations. Unlike the developing world where children are at the greatest risk, 83% percent of deaths attributed to acute diarrhea occur in adults greater than 65 years old. Norovirus (caliciviruses), of which more than 100 different strains are identified, independently accounts for 50% of diarrheal illnesses in the United States. Media headlines continue to highlight outbreaks of infectious diarrhea on cruise ships and in nursing homes, schools, and hospitals. Hospital-acquired *Clostridium difficile* and norovirus infection are the most prevalent causes of fatal illness from diarrhea. Diarrhea continues to be a source of hours of lost work and a cause of significant morbidity and mortality.

In the United States, *C. difficile* infection has become a leading cause of gastroenterologic hospitalization and death accounting for direct annual costs of 3.4 billion dollars. There has been an increase in both incidence and severity of *C. difficile* infection in the last decade. Intravenous (IV) administration of antibiotics prior to emergency department (ED) discharge has been associated with an increase in antibiotic-associated diarrhea. Vulnerable populations at risk of life-threatening illness include patients at the extremes of age, the immunologically compromised, and those with iatrogenic disease.

**Pathophysiology**

Diarrhea is defined as a change in normal bowel movements with passage of three or more stools per day or at least 200 g of stool per day. Acute diarrhea lasts for 14 days or less, persistent diarrhea is defined as lasting for greater than 14 days, and chronic diarrhea continues for 30 days or longer.

Diarrhea-associated illnesses are divided into two main categories: infectious and noninfectious. Infectious causes of diarrhea account for 85% of cases, with noninfectious causes accounting for the remainder. Causes of infectious diarrhea include viruses (70%), bacteria (24%), and parasites (6%) (Box 28.1).

Acute diarrhea presentations are usually infectious and self-limited. They are generally caused by viral or bacterial pathogens.

Persistent diarrhea often results from enteric pathogens that are bacterial or protozoan. Chronic diarrhea is frequently noninfectious and consequently requires further investigation to determine its source.

The small and large bowels absorb 99% of daily gastrointestinal tract secretions produced and liquids ingested. Reducing water absorption by 1% can result in diarrhea. Four major pathologic processes can contribute to this decreased absorption in the gut:

- **Secretory diarrhea** is caused by pathogens that produce cytotoxins, which can increase cellular permeability leading to the oversecretion of water and electrolytes. The majority of ED presentations of diarrhea result from this pathologic secretory process. Medications, endocrine disorders, and neoplasms constitute several of the noninfectious causes of secretory diarrhea (Box 28.2).

- **Inflammatory diarrhea** (invasive or dysentery) is attributed to another distinct pathologic mechanism. Cellular damage of the intestinal mucosa leads to hypersecretion of water, electrolytes, blood, mucus, and plasma proteins. Most frequently, inflammatory diarrhea is caused by invasive bacterial and parasitic pathogens (see Box 28.1). Noninfectious causes of inflammatory diarrhea consist of chemotherapy, radiation therapy, inflammatory bowel disease, and autoimmune disorders. Systemic symptoms, fecal leukocytes, and fecal erythrocytes are typically present on evaluation.

- **Osmotic diarrhea** occurs with the ingestion or malabsorption of osmotically active solutes. The solutes themselves lead to the movement of water into the intestinal lumen, and the gut is unable to reabsorb this massive volume. Osmotic laxatives and the effect of carbohydrate malabsorption are examples of this process. Steatorrhea results from the osmotic effects of lipids not absorbed in malabsorption and maldigestion syndromes.

- **Abnormal motility** is yet another mechanism that may cause diarrhea. However, although usually a component of chronic diarrhea, it can also play a role in presentations of acute diarrhea. Hypermotility decreases the contact time between luminal contents and the absorbing mucosa. The consequence of which is limited water and electrolyte reabsorption.

**Diagnostic Approach**

A thorough patient evaluation includes inquiries regarding travel, immunizations, medications, recent antibiotic use, hospitalization, and sick contacts. Duration of symptoms, volume, frequency, consistency or presence of blood in the stool, ability to tolerate oral intake, and accompanying systemic symptoms, such as fever, vomiting, or abdominal pain are key components in the patient assessment. Social history should include contact with nursing home residents, hospital employment, or exposure to those who are immunocompromised.

**Differential Diagnosis Considerations**

The differential diagnosis of a patient presenting with diarrhea to the ED can be categorized as acute infectious or chronic diarrhea.
Box 28.1

Causative Agents of Infectious Diarrhea

**Viral (60% of cases)**
- Astrovirus
- Calicivirus
- Coronavirus
- Cytomegalovirus
- Enteric adenovirus
- Hepatitis A through G
- Herpes simplex virus
- HIV enteropathy
- Norwalk-like agents
- Norwalk virus
- Pararotavirus
- Picornavirus
- Rotavirus
- Small round viruses

**Bacterial (20% of cases)**

**Invasive**
- Aeromonas species
- Campylobacter species
- Clostridium difficile
- Entero invasive Escherichia coli
- Mycobacterium species
- Plesiomonas shigelloides
- Salmonella species
- Shigella species
- Vibrio fluvialis
- Vibrio parahaemolyticus
- Vibrio vulnificus
- Yersinia enterocolitica
- Yersinia pseudotuberculosis

**Toxigenic**

Poisoning With Preformed Toxins
- Bacillus cereus
- Clostridium botulinum
- Staphylococcus aureus

**Other Bacteria**

Parasitic (5% of cases)
- *Parasites*
- Balantidium coli
- Blastocystis hominis
- Cryptosporidium
- Cyclospora
d- Entamoeba histolytica
- Entamoeba polecki
- Enteromonas hominis
- Giardia lamblia
- Isospora belli
- Microsporidia
- Sarcocystis hominis

Helminths
- Angiostrongylus costaricensis
- Anisakiasis
- Ascaris lumbricoides
- Diphyllobothrium latum
- Enterobius vermicularis
- Hookworms
- Schistosoma species
- Strongyloides stercoralis
- Taenia species
- Trichinella spiralis
- Trichuris trichiura

HIV, Human immunodeficiency virus.

*% indicates the estimated contribution to total cases.

*Associated with fever, abdominal pain, and fecal red blood cells or white blood cells.

Box 28.2

Causes of Noninfectious Diarrhea

**Toxins**

**Drugs**

- ACE inhibitors
- Alprazolam (Xanax)
- Antacids (magnesium)
- Antibiotics
- Antidepressants
- Antiepileptic drugs
- Antihypertensives
- Antiparkinson drugs
- Beta-blockers
- Caffeine
- Cardiac antiarrhythmics
- Chemotherapy agents
- Cholesterol-lowering drugs
- Cholinergic agents
- Cholinesterase inhibitors
- Colchicine
- Digitalis
- Diuretics
- Fluorouracil
- Fluoxetine (Prozac)
- Histamine H2-receptor antagonists
- Hydralazine
- Lactulose
- Laxatives, cathartics
- Levodopa
- Lithium
- NSAIDs
- Neomycin
- Podophyllin
- Procainamide
- Prostaglandins
- Quinidine
- Ricinoleic acid
- Theophylline
compromising infectious and noninfectious etiologies. Most viral and many bacterial agents cause self-limited secretory diarrhea that lasts less than 14 days and results in mild dehydration with minimal systemic symptoms. In the United States, one quarter of diarrheal presentations to the ED result from norovirus infection. Bacterial and protozoal agents less commonly cause diarrhea syndromes indistinguishable from norovirus infection with a non-toxic, self-limited course. Bacteria, parasites, and rarely viruses are the source of infectious persistent or chronic diarrhea. Bacterial pathogens include *Aeromonas*, *Campylobacter*, *C. difficile*, *Salmonella*, and *Mycobacterium tuberculosis*. *C. difficile* infection, once considered a nosocomial infection in the elderly population, is now reported in healthy ambulatory patients without recent antibiotic use. Evidence indicates that an increase in virulence and alterations in gut flora have resulted in colonization by antibiotic resistant *C. difficile*. Parasitic sources that infect the colon include *Amoeba*, *Trichuris*, *Yersinia*, and *Schistosoma* species. *Giardia*, *Cryptosporidium*, *Cyclospora*, *Isospora*, and *Strongyloides*...
are pathogens affecting the small intestine. Homosexual men have an increased probability of complicated protozoal diarrhoea syndromes caused by *Giardia lamblia* and *Entamoeba histolytica*. Organ transplant patients are at increased risk compared to the general population for complicated diarrhea from *Cytomegalovirus*.

Chronic diarrhea in developing countries is most frequently attributed to a bacterial source. Conversely, in developed countries it is often caused by noninfectious disorders, such as irritable bowel syndrome, laxative abuse, malabsorption syndromes, and inflammatory bowel disease. Patients with human immunodeficiency virus (HIV) may initially present with chronic diarrhea. *Cryptosporidium, Microsporidia, Mycobacterium avium* complex, herpes simplex virus, *Isospora, Cyclospora*, and *Cytomegalovirus* are possible sources of chronic infectious diarrhea. Parasitic and helminthic infections are additional considerations.

There are numerous causes of noninfectious diarrhea (see Box 28.2), accounting for 15% of all cases of diarrheal illness. Clinically, it is often challenging to distinguish between infectious and noninfectious causes. Gastrointestinal bleeding, ischemic bowel, acute appendicitis, intussusception, ectopic pregnancy, and partial bowel obstruction all may present with diarrhea. The differential diagnosis for noninfectious diarrhea is lengthy, including toxic exposures or ingestions, adrenal insufficiency, hyperthyroidism, and hormone secreting tumors.

**Pivotal Findings**

**Signs and Symptoms**

Initial assessment of the patient focuses on oxygenation and perfusion with attention to volume status. Indications of hypovolemia and hypoperfusion include tachycardia, hypotension, dry mucosa, cool extremities, diaphoresis, poor skin turgor, decreased urine output, and mental status changes. Clinical signs and symptoms of anemia are pale conjunctiva, delayed capillary refill, pallor, and shortness of breath. A diarrhea associated acid-base disorder is suspected in patients with increased respiratory rate or Kussmaul’s respirations. Patients presenting with systemic inflammatory response syndrome (SIRS) may be dehydrated or in septic shock. Bedside ultrasound can be employed to assess volume status. A patient with a collapsed inferior vena cava and a poorly filled, rapidly beating heart requires intervention and rehydration. Young, healthy adults may maintain a normal blood pressure and heart rate even in the setting of severe dehydration. The heart rate in patients who are taking anti-arrhythmic medications, beta-blockers or have pacemakers may be an unreliable indicator of volume status. Clinical signs of dehydration in the pediatric patient include sunken eyes, depression of the fontanel, reduced number of wet diapers, and decrease in alertness or activity. Following stabilization, a secondary survey is conducted in an attempt to further evaluate the patient and direct treatment.

The secondary survey assesses the patient’s overall health condition, including the presence of fever and the potential for an acute abdomen. Focal abdominal pain in the setting of gastrointestinalitis may mimic an acute surgical abdomen. Serial abdominal examinations are often required. Rectal examination can detect melena, hematochezia, or fecal impaction. Gross blood may be indicative of invasive, infectious diarrhea, although there are other pathologic states that manifest with gastrointestinal bleeding, including inflammatory bowel disease. Parasitic infection may be accompanied by histamine-induced changes, such as urticaria or bronchospasm. Systemic findings of jaundice or scleral icterus demonstrate associated liver pathology. Clinical presentations of toxic syndromes (eg, cholinergic or sympathomimetic) may include diarrhea.

**Ancillary Testing**

In most cases of acute diarrhea, laboratory and diagnostic tests should be kept to a minimum. Testing is guided by the clinical severity of the illness, including abnormal vital signs, presence of comorbidities, or physical examination findings suggesting serious intra-abdominal disease or diarrhea related to serious systemic illness. A toxic appearance with fever, volume depletion, blood-containing or mucus-containing stools, frequent voluminous stools, peritoneal findings, and serious comorbidities, especially immune suppression or chronic inflammatory gastrointestinal disease, should prompt further investigation in order to guide appropriate therapy.

**Blood Tests.** Leukemoid reactions have been reported in *C. difficile* infections, although an isolated white blood cell count is not sensitive or specific enough to aid in diagnostic decision making. Eosinophilia may be seen in parasitic infections with an extra-intestinal migration phase. Hemoglobin levels may be employed to screen for anemia secondary to blood loss. Abnormalities in platelets and coagulation may aid in identifying causes for gastrointestinal bleeding. A simple chemistry panel to check electrolytes and a blood urea nitrogen/creatinine ratio can be useful when hypovolemia is suspected or there has been substantial diarrhea. Liver function tests including aspartate transaminase (AST), alanine transaminase (ALT), and coagulation times are indicated when there is jaundice or other evidence of liver disease. Other laboratory studies are rarely indicated but may be obtained when there are particular findings. For example, a lipase level is indicated if the diarrhea is part of a syndrome that includes severe epigastric pain and tenderness accompanied by vomiting.

**Lactate.** An elevated lactate may aid in identifying and directing therapy in patients with dehydration, severe sepsis, or causes of noninfectious diarrhea (eg, mesenteric ischemia, gastrointestinal bleeding).

**Hemoccult and Fecal Cell Count.** Fecal leukocytes are not specific or sensitive enough as the sole criteria to determine which patients should be treated with antibiotics. Inflammatory diarrhea of varied causes, including bacterial or parasitic infection and noninfectious sources, may demonstrate red and white blood cells visualized on stool examination. The presence of fecal leukocytes does not identify which patients would benefit from empirical antibiotic therapy. A positive stool guaiac should not be used in isolation to initiate antibiotic therapy. Blood without fecal leukocytes is present in amebiasis, malignancy, fissures, hemorrhoids, bowel ischemia, and primary gastrointestinal bleeding.

**Assays for Fecal Calprotectin and Fecal Lactoferrin.** The assays for fecal calprotectin and fecal lactoferrin produced by leukocytes are not indicated. These tests are not useful in guiding ED patient evaluation, treatment, or disposition, even though they are reasonably sensitive markers, 83% and 75% respectively, of acute bacterial diarrhea.

**Clostridium difficile** *Toxin Assay.** This test is indicated if the patient is immunocompromised, or reports recent antibiotic use, hospitalization, nursing home residence, or employment in a health care setting, or significant diarrhea (≥6/day) for several days. Diarrhea associated with *C. difficile* most commonly occurs during or closely following the completion of the antibiotic course. Cephalosporins, penicillins, and clindamycin are most frequently implicated, but all antibiotic use places patients at risk for an infection. Quantitative polymerase chain reaction (PCR) is the most sensitive functional toxin assay and is the assay of choice for diagnosis of *C. difficile* infection.
**Escherichia coli O157:H7 Toxin Assay.** This assay is indicated when there is a known outbreak or if the presentation occurs in an endemic area. The assay also is indicated for patients with suspected hemolytic-uremia syndrome.

**Stool Culture for Bacteria.** Tests for pathogenic enteric bacteria including *Campylobacter, Salmonella,* and *Shigella* species using a sterile sample are generally not indicated in the ED, given their low sensitivity and delayed results. However, the tests are helpful for patients being admitted to hospital with toxic appearance, immunocompromise, or advanced age. Stool culture also is indicated for patients with persistent or chronic diarrhea not previously tested for these pathogens.

**Stool Examination for Ova and Parasites.** These tests generally are not indicated in the ED. They may be useful in patients with chronic diarrhea (*E. histolytica* and *Cryptosporidium*), patients with history of travel to, or recent immigration from, developing countries (*Cryptosporidium, Giardia,* and *Cyclospora*), patients with exposure to infants in daycare centers (*Cryptosporidium* and *Giardia*), and patients with HIV infection (*E. histolytica* and *Giardia*).

**Giardia Antigen Assay and Serologic Testing for Amebiasis.** *Giardia* antigen assay and serologic testing for amebiasis are indicated for patients exposed to poor sanitation, those with immune compromise, a history of travel to developing countries, recent camping with ingestion of stream or spring water, and those with daycare exposures.

**Radiographic Studies.** Plain radiography rarely is indicated. If peritonitis is present and abdominal perforation is suspected, abdominal computed tomography (CT) scan with (at least) IV contrast is the imaging modality of choice. If intestinal obstruction is suspected, an abdominal plain film may confirm the diagnosis but should only be done if there is certainty that more specific causative diagnosis by CT scan will not be required. If specific diagnosis is required, the abdominal plain film is omitted and CT scan is performed. CT, similarly, is useful for diagnosis of fistula, mesenteric ischemia, inflammatory bowel disease, and acute surgical diagnoses, such as appendicitis. If biliary disease is suspected, abdominal ultrasound is preferred to CT scan, and ultrasound can often diagnose appendicitis without the need for ionizing radiation.

**Gastrointestinal Referral.** Patients with chronic diarrhea should be referred to their primary care doctor or a gastroenterologist for further diagnostic testing, much of which is beyond the scope of the ED (endoscopy, biopsy, stool studies).

**DIAGNOSTIC ALGORITHM**

Unlike many presenting symptoms and signs, critical and emergent diagnoses for patients with diarrhea depend much more on the effects of the diarrhea (hypovolemia, renal compromise) and patient comorbidity (immune compromise, advanced age, inflammatory bowel disease) than on the cause of it.

**Critical Diagnoses**

Patients with diarrhea and unstable vital signs are suspected of having a critical condition and are evaluated for hypovolemic, septic, or hemorrhagic shock, and drug toxicity (eg, cholinergic poisoning). They require rapid resuscitation, including IV fluids, while the underlying etiology is investigated. Laboratory studies should include a creatinine to assess renal status, hemoglobin to assess for gastrointestinal bleeding or hemocoagulation, and a lactate to assess for organ perfusion. An elevated white blood cell count is nonspecific but can be associated with *C. difficile* infection, invasive causes of diarrhea, or simply the stress effects of the illness and volume loss. Even viral infectious diarrhea perceived as “self-limited” may result in life-threatening illness in those patients presenting with severe dehydration.

If vomiting accompanies diarrhea or if the patient appears jaundiced, liver function tests may help delineate other causes of diarrhea, including infectious hepatitis. At particular risk are the elderly, pediatric populations, and the immunocompromised. Plain films are of little or no use, but CT imaging of the abdomen is indicated if perforation or major vascular disease (aorto-enteric fistula, bowel ischemia) is suspected.

**EMPIRICAL MANAGEMENT**

Oral rehydration is the treatment choice for mild fluid losses (see Fig. 28.1) and can be accomplished with sports beverages, commercial rehydration solutions, or a balanced clear liquid diet at home. For less developed areas, the WHO has outlined an oral rehydration solution (WHO-ORS) that can be made by dissolving the following in 1 L of clean water: 3.5 g of sodium chloride, 2.9 g of sodium citrate, 2.5 g sodium bicarbonate, 1.5 g of potassium chloride and 20 g of glucose or 40 g of sucrose. Studies in infants 7 to 120 days with probable sepsis and diarrhea demonstrate that 10 mg daily oral zinc supplementation combined with antibiotic therapy improves outcomes.9

The choice of rehydration fluids is dependent on the extent of dehydration and the underlying health of the patient. In otherwise healthy patients with mild dehydration, fluids including sports drinks and diluted fruit juices may be supplemented with soups, broths, or crackers. However, these “clear liquids” may contain excess sugars and insufficient sodium content, resulting in an osmotic diarrhea. Caffeine should be avoided because it increases cyclic adenosine monophosphate levels and may lead to a secretory diarrhea.

Pathogens responsible for acute diarrhea may rarely cause a transient lactase deficiency causing malabsorption and osmotic diarrhea if milk is ingested. Patients should be cautioned that if persistent diarrhea appears to be related to dairy product ingestion, these products should be avoided for 2 weeks. Foods that have high fat content delay gastric emptying. The BRAT (bananas, rice, apples, toast) diet is often recommended, because it is relatively constipating (bananas, apple peel) and nonstimulating (bland diet). The pectin, such as is found in apple peel, is the

---

**Emergent Diagnoses**

In patients who have stable vital signs and are nontoxic appearing, the duration of diarrhea guides the ED evaluation (Table 28.1). In elderly patients, those with recent hospitalization, or history of being immunocompromised, laboratory evaluation includes testing for electrolyte levels and renal function and for *C. difficile*, which often is undiagnosed on first presentation (Fig. 28.1). Discussion with the patient's physician regarding presentation, evaluation, and plan is important to coordinate follow-up and outpatient monitoring, especially for patients with multiple comorbidities. Well appearing patients that do not have any concerning findings or risk factors (history of immunosuppression, recent hospitalization, nursing home stay) do not need any laboratory testing or intervention. In these patients, the specific causative diagnosis for the diarrhea illness is not important, because the treatment is supportive and the course is generally self-limited. Well appearing patients with low-grade fever do not require testing in the ED unless *C. difficile* is suspected, but outpatient follow-up should be arranged and strict return precautions should be provided.

DM, diabetes mellitus; EPEC, enteropathogenic E. coli; HIV, human immunodeficiency virus; WBC, white blood cell.
In the treatment of patients with recurrent *C. difficile* infections, antibiotic treatment of severe gastroenteritis in children has been associated with the development of hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura in those testing positive for enterohemorrhagic *E. coli* O157:H7, *Salmonella*, *Shigella*, and *Campylobacter* have also been implicated. Pediatric patients should initially be given supportive care and, if possible, antibiotic therapy should be tailored to culture results.

Nontoxic patients with acute viral gastroenteritis may benefit from antimotility agents and often obtain significant relief of symptoms. In adults, an initial dose of loperamide 4 mg orally with subsequent doses of 2 mg (not to exceed 16 mg in 24 hours) is the safest and most effective medication with relief of symptoms achieved more rapidly than with bismuth subsalicylate (Pepto-Bismol). In the pediatric population, the use of loperamide or diphenoxylate with atropine has rarely been associated with the precipitation of toxic megacolon and hemolytic-uremic syndrome. Antimotility agents should be used with caution in patients who are high risk (such as, the elderly) and those with recent hospitalization or antibiotic use.

Probiotics have been proposed as an alternative to antibiotic therapy for diarrhea, although as of yet there is no consensus on dosage or frequency of specific products. Oral ingestion of lactobacillus and other bacteria are effective in restoring the normal gastrointestinal flora that is disrupted during diarrhea illness. The use of probiotics appears to reduce stool frequency and shorten the duration of acute infectious diarrhea by 1 day. Evidence demonstrates a protective effect of probiotics in preventing *C. difficile*–associated diarrhea. It is safe and effective when used as an adjunct to antibiotics in immunocompetent patients.

The causative agent of diarrhea is often not identified in the ED and an empirical management strategy is needed. Patients with uncomplicated, acute diarrhea can be discharged home after careful assessment and symptomatic treatment. Viral agents and many forms of bacterial gastroenteritis are self-limited with patients requiring supportive therapy. Following initial resuscitation, hospitalization is necessary in patients with severe dehydration, hemodynamic instability, or toxic appearance. Intensive care unit (ICU) level of care is recommended in patients presenting in septic shock or severe sepsis despite continued resuscitation. In patients with multiple comorbidities who are being discharged home with likely uncomplicated diarrhea, it is imperative to arrange for outpatient follow-up. Outlining specific return precautions to the ED is essential prior to the discharge of any patient.
Diarrhea

Stable vital signs
- No

Unstable vital signs
- Yes

Resuscitation
- fluids, labs, imaging, consultation if necessary

Discharge home
- No

Yes

Vulnerable population*
- Abnormal PE

Discharge with urgent follow-up
- No

Acute lab/imaging abnormality
- No symptomatic improvement

Consider observation unit vs. floor admission

Hemodynamic stability
- (may include abnormal studies)

No

Yes

Floor admission

ICU

*Immunocompromised, elderly, recent antibiotic use (see Table 28.1)

Fig. 28.2. Approach to disposition. ICU, Intensive care unit; PE, physical examination.

**KEY CONCEPTS**

- Hospital acquired *C. difficile* and norovirus infection are the most prevalent causes of fatal illness from diarrhea in the United States.
- Key elements of the history in the patient with diarrhea include recent travel, immunosuppression, hospitalization, and antibiotic use.
- Acute diarrhea is most often viral and treated with supportive therapy.
- Fluids with excess sugar, caffeine, and high fat content should be avoided in patients with diarrhea.
- In nontoxic patients, loperamide, initial dose of 4 mg and subsequent doses of 2 mg after each loose stool (not to exceed 16 mg in 24 hours), is safe and effective in providing symptom control.
- Ciprofloxacin 500 mg orally twice daily or levofoxacin (Levaquin) 500 mg once daily are effective empirical treatments for systemically ill appearing adults with suspected traveler’s diarrhea.
- *C. difficile* treatments include metronidazole 500 mg orally three times daily for 10 to 14 days as initial treatment or vancomycin 125 mg four times daily orally for 10 to 14 days.
- Quantitative PCR is sensitive in testing for *C. difficile*.
- Use of probiotics reduces stool frequency and shortens duration of acute infectious diarrhea.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Ilness are infectious and noninfectious. Infectious causes represent only 15%. By far, the most common pathogens causing diarrhea but is always a component of acute diarrhea. Hypermotility decreases contact time between luminal contents and the absorbing mucosa, thereby limiting water and electrolyte absorption. Absorption of osmotically active solutes cause the osmotic shift of water into the intestinal lumen. Inflammatory diarrhea, also described as invasive diarrhea or dysentery, results from cellular damage to the intestinal mucosa, leading to the secretion of water, electrolytes, blood, mucus, and plasma proteins. Osmotic diarrhea occurs with the ingestion or malabsorption of osmotically active solutes. These solutes cause the osmotic shift of water into the intestinal lumen to the extent of overwhelming the gut’s ability to reabsorb it. Abnormal motility is generally seen in patients with chronic diarrhea but is always a component of acute diarrhea. Hypermotility decreases contact time between luminal contents and the absorbing mucosa, thereby limiting water and electrolyte absorption.

28.3. An otherwise healthy 25-year-old man presents with a 3-day history of diarrhea. He reports associated anorexia, weight loss, shortness of breath, and itching. On physical examination, he is noted to have diffuse erythematous wheals on his skin, and pulmonary examination reveals bilateral wheezing. Of the following, which is the most likely cause of his diarrhea?

A. Bacillus cereus
B. Enteric adenovirus
C. Giardia lamblia
D. Rotavirus
E. Vibrio vulnificus

Answer: C. Hives and bronchospasm in this patient point to excessive histamine release. In the setting of diarrhea, histamine release would most likely result from a parasitic infection. This is not common; however, it should be considered in patients presenting with diarrhea and histamine-induced skin changes. Of the choices listed, Giardia lamblia is the only parasite.

28.4. Evaluation of stool for ova and parasites would prove least beneficial in which of the following subsets of patients presenting with diarrhea?

A. Patients concurrently taking clindamycin
B. Patients returning from a trip to Russia
C. Patients with chronic diarrhea
D. Patients with human immunodeficiency virus (HIV) infection
E. Patients working in daycare centers

Answer: A. The assessment of stool for ova and parasites is not routinely recommended in most cases of diarrheal illness. This study is used in patients with chronic diarrhea (Entamoeba histolytica and Cryptosporidium); patients with a history of travel to developing countries, particularly to Nepal or areas of Russia (Cryptosporidium, Giardia, and Cyclospora); patients with exposure to infants in daycare centers (Cryptosporidium and Giardia); and patients with HIV infection (E. histolytica and Giardia). Patients with diarrhea who are concurrently taking clindamycin would benefit most from testing for Clostridium difficile toxin.

28.5. Which of the following antibiotics is recommended for the empirical treatment of systemically ill-appearing adults with diarrhea?

A. Azithromycin
B. Ciprofloxacin
C. Metronidazole
D. Trimethoprim-sulfamethoxazole
E. Vancomycin

Answer: B. The current recommendation for empirical treatment of a systemically ill-appearing adult is ciprofloxacin 500 mg orally twice a day or levofloxacin 500 mg orally every 24 hours for 3 to 5 days. Fluoroquinolones are efficacious against most organisms.
that cause dysenteric illnesses and have been shown to be more effective than trimethoprim-sulfamethoxazole. Fluoroquinolones should not be administered to pregnant patients or children younger than 18 years old.

28.6. Which of the following causes of diarrhea is more common among children who attend daycare than among those who do not?
A. Campylobacter
B. Escherichia coli
C. Salmonella
D. Shigella
E. Yersinia

Answer: D. Daycare attendance increases the probability of a patient having non-benign diarrhea caused by Shigella, Giardia, or rotavirus.

28.7. Homosexual men are at increased risk of diarrhea caused by which of the following protozoal pathogens?
A. Blastocystis hominis
B. Cryptosporidium

Answer: C. Giardia lamblia
D. Isospora belli
E. Microsporidia

Answer: C. Homosexual men have increased probability of complicated protozoal diarrhea syndromes caused by Giardia lamblia and Entamoeba histolytica.

28.8. Compared with the general population, diarrheal illnesses in organ transplant patients are more frequently caused by which of the following?
A. Coronavirus
B. Cytomegalovirus
C. Herpes simplex virus
D. Norwalk virus
E. Rotavirus

Answer: B. Patients with organ transplants are at increased risk for complicated diarrhea caused by Cytomegalovirus.
**PRINCIPLES**

The term *constipation* refers to a symptom or complex of symptoms and not a specific diagnosis. Patients and health care providers often define constipation differently. Most health care providers define constipation based on stool frequency. Patients often use the term *constipation* to describe a broad set of complaints, including straining, hard or infrequent stools, pain during a bowel movement, a feeling of incomplete evacuation, or abdominal bloating. Constipation may be acute (new for the patient) or chronic. *Chronic constipation* is defined as the presence of symptoms for at least 3 months. In clinical practice, attempting to identify the cause of the symptoms often results in the best chance of effective treatment and helps determine disposition. A definitive diagnosis often is not possible in the emergency department (ED), and appropriate follow-up evaluation should be arranged. When constipation becomes severe with constant pain, some clinicians use the term *obstipation*. Obstipation represents the progression of the symptom of constipation toward bowel obstruction.

Although constipation may be the final diagnosis for some patients presenting to the ED with abdominal pain, providers should be cautious when reaching this conclusion. Other more serious causes of abdominal pain must be excluded, especially when a patient has abnormal vital signs or marked or localized tenderness on physical examination of the abdomen.

**Epidemiology**

In adults, constipation is more common in women, the elderly, those with high body mass index, sedentary individuals, and those with low socioeconomic status. A consistent trend of increasing prevalence of constipation is observed with age, with significant increases after the age of 70 years. The high prevalence among elderly patients is multifactorial and related to a diet low in fiber, sedentary habits, multiple medications, and various disease processes that impair neurologic and motor control.

**Pathophysiology**

Normally the gastrointestinal tract is presented with 9 to 10 L/day of secretions and ingested fluids. The small intestine usually absorbs all of this except for approximately 500 mL. The colon mixes the ileal effluent, ferments and salvages the unabsorbed carbohydrate residues, and desiccates the contents to form stool. The process of stool transport and evacuation is complex and is regulated by neurotransmitters, intrinsic colonic reflexes, and a multitude of learned and reflex mechanisms that are not fully understood. Constipation may result from structural, metabolic, mechanical, neurologic, or behavioral disorders that affect the colon or anorectum either directly or indirectly.\(^1\)\(^-\)\(^3\)

**DIAGNOSTIC APPROACH**

**Differential Diagnosis Considerations**

Causes of constipation are divided into *primary* (no apparent external cause) and *secondary* causes (Box 29.1). These two groupings have some overlap. In the ED, patients most commonly have acute constipation resulting from side effects of medications or avoidance of defecation secondary to presence of painful perianal lesions, such as fissures, hemorrhoids, or perirectal abscesses. Ruling out emergent conditions related to constipation is the priority. Severe, chronic constipation causing fecal impaction in the large bowel leading to pressure necrosis and perforation can cause a condition referred to as *stenal perforation*.\(^1\) This is typically diagnosed on computed tomography (CT) scan.

**Pivotal Findings**

**Symptoms**

A thorough, detailed history usually identifies the most likely cause of the patient’s constipation. Start by defining what the patient means by “constipation.” Essential information includes the presence or absence of serious symptoms and signs, such as fever, anorexia, nausea, vomiting, blood in the stool, anemia, weight loss of more than 10 pounds, a family history of colon cancer, onset of constipation after the age of 50, and acute onset of constipation in an elderly patient. Diet and dietary changes are noted.

Additional elements of the history are directed toward elucidating a possible cause. Questions about the character of the stools may reveal a decrease in caliber of the stool, suggesting possible mass lesion, or diarrhea alternating with constipation, which may indicate irritable bowel syndrome. The review of systems should include questions regarding associated symptoms if no obvious cause is elicited in the history. Questions directed at associated neurologic symptoms, activity level, and status of comorbid diseases may provide clues to contributing factors. A medication history should include any recent changes in dosage of any prescription medications, herbal agents, and over-the-counter (OTC) medications.

Many patients experience constipation as a side effect of a medication or drug of abuse with opioids being the most commonly implicated. Because elderly patients are at particular risk for constipation and are sometimes prescribed opioids for pain, they are a particular group who should be warned about constipation and given instructions to prevent and treat it. Other drugs that may cause constipation include iron supplements, calcium channel blockers, and antidepressants.

**Signs**

The physical examination should begin with a general inspection of body habitus and nutritional status and then focus on the
abdominal and rectal examinations. The abdominal examination in constipation is usually normal, and abnormal findings (such as, tenderness, a mass, distention, or possibly evidence of obstruction) prompt further directed evaluation. Bowel sounds should be auscultated and typically are normal.

Anorectal inspection may reveal fissures, hemorrhoids, or rectal prolapse. The digital rectal examination should include palpation for impacted stool or mass, and the presence or absence of pain should be noted. Having the patient bear down may be helpful in assessing sphincter function and may reveal milder forms of prolapse. The quantity and the characteristics of the stool should be recorded. Testing the stool for occult blood may yield additional information, although straining with stooling can produce local anal lesions and bleeding. If results of occult blood testing are positive, diverticular disease, carcinoma, and local anal bleeding from repeated attempts at straining all are possibilities. The rectal examination alone should not be used to confirm or exclude the presence of constipation.

Ancillary Testing

The majority of patients who visit the ED with a chief complaint of constipation do not need any testing. Plain abdominal radiography is of almost no value, and patients whose history and examination suggest a need for imaging should undergo ultrasound or CT scan, depending on the working differential diagnosis. Although constipation can cause cramping and abdominal pain, plain radiographs documenting an increased stool load in the constipated patient should not be used to rule out more serious underlying causative disorders, especially if the patient has a significant amount of abdominal pain or tenderness on examination. Several studies have shown that interpretation of abdominal films in the evaluation of constipation is highly variable, subjective, and can lead to misdiagnosis. 1,5

Clinical laboratory studies are not routinely indicated in the evaluation of constipation. When blood is found in the stool, a hemoglobin level or complete blood count (CBC) may reveal an accompanying anemia, which may suggest an occult carcinoma or recurrent blood loss from localized colon disease, like diverticulosis. The white blood cell count is nonspecific and not helpful. Patients with acute constipation for which the cause is not readily apparent should receive symptomatic treatment, with referral for outpatient evaluation and reassessment as needed. The patient in the ED with chronic constipation and no alarming signs or symptoms should receive empirical treatment without any ancillary testing. Outpatient tests may eventually include blood tests to investigate metabolic or endocrine causes and possibly specialized tests, such as colonic transit studies and anorectal manometry.2

**DIAGNOSTIC ALGORITHM**

The approach to the patient with constipation starts with assessing whether or not this symptom is accompanied by the additional symptom of abdominal pain. If such pain is present, the evaluation should be geared toward this symptom, which may ultimately reveal the cause of the constipation. Constipation may itself cause abdominal pain; however, this should be a diagnosis of exclusion once other, more serious potential causative disorders have been ruled out.

Further episodes of constipation may include recommending increased fluid intake, increased exercise, increased dietary fiber, and, if necessary, additional sources of bulk in the form of synthetic bulking agents. These interventions will not usually help the acutely constipated patient in the short term. Therapeutic choices and recommendations for patients should be customized based on patient preferences, as well as history of efficacy of treatments used in the past. Specific recommendations may also include withholding a causal medication, management of an anal fissure, or draining of a perirectal abscess. Stool softeners (e.g., docusate sodium), although commonly recommended to patients, should not be used as a first-line agent for most patients with constipation. Docusate has not been shown to be any more effective than placebo in relieving acute constipation, although it may be somewhat helpful in patients with anal fissures or hemorrhoids, because it may make defecation less painful.¹

Specific agents for symptomatic treatment of constipation are listed in Table 29.1. There are five main classes of commonly used laxatives. These are softeners, bulking agents (fiber), osmotic agents, stimulants, and the new peripherally acting µ-opioid.

**EMPIRICAL MANAGEMENT**

Treatment of acute constipation is directed toward identifying the underlying cause and providing symptom relief. Prevention of further episodes of constipation may include recommending increased fluid intake, increased exercise, increased dietary fiber, and, if necessary, additional sources of bulk in the form of synthetic bulking agents. These interventions will not usually help the acutely constipated patient in the short term. Therapeutic choices and recommendations for patients should be customized based on patient preferences, as well as history of efficacy of treatments used in the past. Specific recommendations may also include withholding a causal medication, management of an anal fissure, or draining of a perirectal abscess. Stool softeners (e.g., docusate sodium), although commonly recommended to patients, should not be used as a first-line agent for most patients with constipation. Docusate has not been shown to be any more effective than placebo in relieving acute constipation, although it may be somewhat helpful in patients with anal fissures or hemorrhoids, because it may make defecation less painful.¹

Specific agents for symptomatic treatment of constipation are listed in Table 29.1. There are five main classes of commonly used laxatives. These are softeners, bulking agents (fiber), osmotic agents, stimulants, and the new peripherally acting µ-opioid.

Figure 29.1 presents a diagnostic algorithm. If the physical examination reveals a structural or mechanical cause (such as, pain from hemorrhoids, fissures, or mass lesion), the appropriate treatment or referral is indicated; the constipation will resolve once the cause is addressed. If no obvious cause is found on examination, then determination of the presence or absence of stool in the rectal vault may be helpful. History will be very helpful in differentiating among causes, such as medication side effect and possible neurologic disease.

Constipation is rarely associated with morbidity or mortality. Most bad outcomes are a result of missed diagnosis of bowel obstruction or perforation. These conditions are generally diagnosed through physical examination, plain radiographs, and CT scan if needed. Surgical consultation is needed for suspected perforation or obstruction.

CIC, Chronic idiopathic constipation; IBS-C, irritable bowel syndrome with constipation; SC, subcutaneously.

Receptor antagonists. These agents aid defecation by decreasing stool consistency, stimulating colon motility, or both. There are also several new pharmacologic classes being used or investigated for the treatment of constipation in specific groups of patients.⁶

A group of patients that often experiences constipation are those who are on chronic, medically necessary medications that cause constipation (eg, opioids in patients with chronic pain or cancer). These patients should be on bowel regimens designed to prevent constipation, which usually include such measures as high levels of dietary fiber (eg, added prunes or figs), as well as daily administration of stimulant laxatives. An advance in the treatment of refractory opioid-induced constipation has been the development of peripherally acting μ-opioid receptor antagonists. There are two drugs in this category—methylaltrexone (Relistor), which is administered subcutaneously, and naloxegol (Movantik), which is orally administered.⁷ These drugs selectively block the gastrointestinal μ-opioid receptors without compromising central mediated effects of opioid analgesia or precipitating withdrawal. The use of this class of drugs in the treatment of opioid-induced constipation was recently supported in a systematic review and can be used in the ED for patients in whom standard therapies have failed.⁸

Enemas are sometimes necessary if laxatives have failed to provide relief or if the patient has a large volume of stool in the lower colon or rectum that cannot be expelled. Warm tap-water enemas are the safest choice. For immediate relief, manual disimpaction may be necessary in some patients, especially in elders with large amounts of stool present in the rectal vault. In rare cases, disimpaction may need to be performed with procedural sedation.
### KEY CONCEPTS

- Constipation is a common patient concern and rarely has an emergent condition associated with it.
- Evaluation of the patient with constipation requires a detailed history (with particular attention to medication history), physical examination (including rectal examination) and rarely requires labs or imaging.
- Treatment of constipation includes addressing underlying etiologies and recommending the correct agent based on the etiology.
- Stool softeners (docusate sodium), although commonly prescribed, are ineffective and are rarely indicated.
- Osmotic agents or stimulants can be used to treat the majority of patients who present with constipation.
- Patients who have a large amount of stool in the rectum can be treated with an enema, which acts by distending the rectum and helps soften the stool to facilitate passage. For some with particularly recalcitrant stool, manual disimpaction may be required.
- Plain abdominal radiographs are of little or no use in diagnosing constipation or other, more serious abdominal disorders that may present as constipation, and should be used highly selectively, if at all.
- Patients with opioid-induced constipation that is refractory to other standard laxatives, may benefit from peripherally acting µ-opioid receptor antagonists.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
29.1. Which of the following statements regarding constipation is correct?
   A. Chronic constipation is defined as the presence of symptoms for at least 2 weeks.
   B. Constipation is a disease is increasing in frequency.
   C. Constipation is more common in men than in women.
   D. Obstipation refers to severe constipation with constant pain.
   E. The incidence of constipation is lower in patients with a high body mass index.

Answer: D. Opioids are the most common class of medications to cause constipation. The other medications listed do not commonly cause constipation as a side effect.

29.4. A 25-year-old human immunodeficiency virus (HIV)-positive man presents with a 3-day history of constipation. He also reports a perianal mass has been slowly increasing in size during the past 3 months and has become painful in the past week. He has no other complaints. Physical examination reveals perianal condyloma acuminata with one area of tenderness, friability, and erosion. There is no evidence of infection, and stool can be palpated in the rectal vault during digital examination. Which of the following oral agents would be most beneficial for the symptomatic improvement of constipation in this patient?
   A. Docusate sodium
   B. Mineral oil
   C. Psyllium
   D. Senna
   E. Sorbitol

Answer: B. Oral mineral oil lubricants are particularly helpful in patients who have acute painful perianal lesions. The softening and coating of the stool can make passage much easier and less painful. Although not listed as an option, another consideration in this patient would be suppositories, which are especially helpful in patients who tend to have trouble expelling soft stool from the rectum. Glycerin suppositories may have a soothing effect and be helpful in patients with constipation caused by local, painful perianal lesions.

29.5. Which of the following agents used in the treatment of constipation is contraindicated in patients who are at increased risk for aspiration?
   A. Magnesium citrate
   B. Mineral oil
   C. Polyethylene glycol
   D. Psyllium
   E. Senna

Answer: B. Mineral oil is contraindicated in patients with swallowing problems or patients particularly debilitated who are at increased risk for aspiration, because this could ultimately lead to lipid pneumonia if aspirated.
Acute Pelvic Pain

Epidemiology

Acute pain caused by pelvic pathology is common, and the presenting complaint may be diffuse or lower abdominal pain, pelvic pain, or low back pain. A patient with chronic pelvic pain may also have an acute process related to the chronic condition or arising de novo.

Over one-third of reproductive age women will experience nonmenstrual pelvic pain. Among diagnoses for women with pain caused by gynecologic disorders in the emergency department (ED), pelvic inflammatory disease (PID) and lower genital tract infections (eg, cervicitis, candidiasis, Bartholin’s abscess) account for almost 50%. Other common diagnoses are menstrual disorders, noninflammatory ovarian and tubal pathology (including cysts and torsion), and ectopic pregnancy. Ectopic pregnancy accounts for up to 20% of diagnoses among women presenting with vaginal bleeding or abdominal pain in the first trimester of pregnancy.

Younger patients and those with multiple sexual partners are more likely to have PID, and a previous episode increases the likelihood of a subsequent episode. The risk of ectopic pregnancy is higher in women who have had PID, pelvic surgery, prior ectopic pregnancy, or are using an intrauterine device. Heterotopic pregnancy is of special concern in women undergoing assisted reproduction. Common nongynecologic diseases such as appendicitis, diverticulitis, urinary tract infection, and urolithiasis remain important considerations in the woman with acute pelvic pain. Box 30.1 lists conditions accounting for most cases of pelvic pain in women.

Some causes of pelvic pain may lead to serious sequelae. PID carries the short-term risk of tubo-ovarian abscess and the long-term risks of impaired fertility, chronic pelvic pain, and increased predisposition to ectopic pregnancy. Rupture of an ectopic pregnancy or hemorrhagic ovarian cyst may be life-threatening. Unrecognized abuse may also have serious or lethal consequences.

Pathophysiology

The female pelvis contains the vagina, uterus, fallopian tubes and ovaries, ureters and urinary bladder, and sigmoid colon and rectum, as well as components of the vascular and musculoskeletal systems. Although pelvic pain often originates from the reproductive organs, it may arise from any structures that lie adjacent to or course through the pelvis. Visceral pain afferents supplying the pelvic organs have common innervation with the appendix, ureters, and colon. Their significant overlap makes accurate localization difficult for both patient and emergency clinician. Pain may be initiated by inflammation, distention, or ischemia of an organ, or by spillage of blood, pus, or other material into the pelvis. Pain may become more localized when the afferent nerves in the parietal peritoneum adjacent to an affected organ are stimulated.

DIAGNOSTIC APPROACH

Differential Considerations

The differential diagnosis of pelvic pain is broad (see Box 30.1). Most causes of pelvic pain fit into three categories: (1) reproductive tract; (2) urinary tract; and (3) intestinal tract. Because a subset of pelvic pain is found only in pregnancy, the pregnancy test is a key branch point in the diagnostic process. Potential pregnancy-related disorders can be divided into complications of early pregnancy and complications that occur further along in pregnancy. Although the specific cause of pelvic pain cannot always be determined at the initial ED visit, an organized approach usually leads to the confirmation or exclusion of disorders most likely to result in significant morbidity and/or mortality.

Pivotal Findings

It is unlikely that any particular finding on history or physical examination, summarized in Table 30.1, is reliable enough to make or exclude a particular diagnosis conclusively, so ancillary testing beyond a pregnancy test is commonly required in the evaluation of patients with acute pelvic pain.

The pelvic examination may at times provide crucial information. However, some findings on bimanual examination are subjective and may be unreliable; they are perhaps most helpful in localizing the process to one side or the other or in helping to plan the initial evaluation. There are not sufficient data to select reliable women in whom the pelvic examination need not be performed, although the pelvic examination may be deferred in patients who are planned to undergo immediate imaging (usually ultrasound) for a suspected critical condition such as ruptured ectopic pregnancy. Depending on imaging results, a subsequent speculum or bimanual pelvic examination may or may not be necessary.

A sequential approach can progressively narrow the diagnostic possibilities until a reasonable provisional diagnosis is reached.

Symptoms

The location of pain and pattern of radiation often are helpful in focusing the differential diagnosis toward a specific cause or group of causes. Lateral pelvic pain is often related to a process in the tube or ovary. However, with right-sided pain, appendicitis is considered, and in left-sided pain (especially in patients >40 years), the differential diagnosis includes diverticulitis and colitis. Urolithiasis may also manifest as lateral pelvic pain, especially when the stone is at the ureterovesicular junction, or as pain radiating to the labia or vaginal area. Central pelvic pain usually is caused by processes involving the uterus, bladder, or both adnexae. Pain radiating to the rectum may be secondary to pooling of fluid or blood in the cul-de-sac. Diffuse pain may occur with a central or bilateral process such as PID or with diffuse peritonitis from infection or intraabdominal hemorrhage.

Information regarding the onset and duration of pain may be useful. Patients with uncomplicated appendicitis (without

**Cystitis**
**Ureteral stone**

Fever and chills are more common with an infectious process. Nausea and vomiting occur more frequently when the process originates within the gastrointestinal tract but may also accompany any pain of visceral origin such as ovarian torsion, ureteral colic, and pregnancy or any severe pain. Dysuria occurs in many local vulvar and vaginal processes such as herpesvirus infection, candidiasis, and other types of vulvovaginitis, but urinary urgency typically signals an irritated bladder or urethra and should focus attention on the urinary tract.

Information about the patient's last menstrual period, pattern of menses, and sexual activity pattern may be useful but does not necessarily exclude pregnancy. In a pregnant patient, the obstetric history may provide some helpful diagnostic clues. Recurrent spontaneous abortion or previous ectopic pregnancy increases the likelihood of these conditions, respectively. Patients who are actively undergoing infertility treatment are at increased risk for ectopic pregnancy, heterotopic pregnancy, ovarian torsion, and ovarian hyperstimulation syndrome. Round ligament pain is usually noted in the second trimester. Postpartum patients are at increased risk for endometritis.

The presence, quantity, and duration of associated vaginal bleeding should be ascertained (see Chapters 31 and 178). In a nonpregnant patient, bleeding may be associated with abnormal uterine bleeding (eg, from PID, ovulatory dysfunction, cancer) or trauma (eg, vaginal laceration due to pelvic fracture, direct vaginal irritation or trauma). In a pregnant patient, bleeding may also be associated with a subchorionic hemorrhage in an otherwise viable pregnancy, ectopic pregnancy, nonviable intrauterine pregnancy (IUP) (which may continue to cause bleeding after expulsion of the uterine contents, especially if any products of conception are retained), or later in pregnancy with placenta previa or abortion. In some cases, the amount of bleeding may be substantial enough to necessitate blood transfusion and surgical intervention. The presence of vaginal discharge (color, consistency, odor) should also be ascertained.

Sexual history is important, with emphasis on recent sexual contact and previous history of sexually transmitted disease. A history of any recent gynecologic procedures should be obtained because the onset of pelvic pain shortly after uterine instrumentation increases the possibility of uterine perforation or infection. All women should be interviewed in private to permit disclosure of sensitive information such as sexual history, pregnancy, recent abortion, and abuse.

</tbody>
</table>
Signs

The physical examination is directed toward the abdomen and pelvis. Pelvic examination is performed in almost all patients, including pregnant patients at less than 20 weeks' gestation. Pregnant patients beyond 20 weeks' gestation with complaints of vaginal bleeding should undergo transabdominal pelvic ultrasound for placental localization before the pelvic examination (see Chapter 178), should have a fetal heart rate measured and documented, and may need timely obstetric consultation.

Abnormal vaginal discharge may be seen in a variety of conditions, including vaginitis, cervicitis, endometritis, PID, and retained foreign body. Cervical motion tenderness usually indicates reproductive tract inflammation but also occurs with irritation of adjacent structures (eg, cystitis, appendicitis). An open os is most consistent with an incomplete or inevitable abortion, but does not definitively exclude an ectopic pregnancy. A large uterus in a nonpregnant patient may indicate fibroids. Fundal tenderness is often difficult to distinguish from cystitis but may suggest PID, endometriosis, or necrotic fibroids. Unilateral adnexal masses and tenderness are suggestive of an ovarian cyst, ectopic pregnancy, tubo-ovarian abscess, or ovarian torsion.

The constellation of cervical motion tenderness, uterine tenderness, and adnexal tenderness is classically associated with PID, although only one sign is required to initiate treatment in certain clinical settings per recent Centers for Disease Control and Prevention (CDC) guidelines (2015).^3^

Ancillary Testing

A pregnancy test is required in almost all patients of childbearing age with a complaint of abdominal or pelvic pain, irrespective of sexual history or reported contraception use. Very few exceptions to this rule exist such as documented hysterosalpingectomy or a woman who is known to be pregnant. A positive test result may indicate current or recent intrauterine or extraterine pregnancy or, rarely, molar pregnancy or cancer. Urinalysis of a clean-catch specimen may identify nitrites and pyuria from a urinary tract infection, or hematuria, consistent with urolithiasis or hemorrhagic cystitis. The absence of hematuria does not exclude the possibility of a ureteral stone, although it lowers the likelihood, and mild pyuria may be seen in extravesicular conditions such as appendicitis. Urinalysis should be performed in all pregnant patients with pelvic pain, even if their symptoms do not include urinary tract complaints, because urinary tract infection, including asymptomatic bacteriuria, is associated with significant morbidity for both mother and fetus.

Patients who may be hemorrhaging internally or externally should have their hemoglobin level checked, and type and cross-matching should be performed if the hemorrhage is substantial. Pregnant patients with concern for fetomaternal transfusion (eg, vaginal bleeding) also require blood typing to identify Rh-negative patients who will require Rh(D) immune globulin.

Bedside ultrasound is a core part of the evaluation of most women with pelvic pain and, along with the history and physical examination, should be considered as an integral part of the initial examination. Patients with a positive pregnancy test result should undergo a bedside ED ultrasound or formal ultrasound examination to evaluate for ectopic pregnancy. Identification of a definite IUP by ultrasound imaging excludes ectopic pregnancy with a high degree of certainty in patients who are not undergoing assisted reproduction. Conversely, a patient with a positive pregnancy test in whom a definite IUP cannot be seen is presumed to have an ectopic pregnancy until proven otherwise. In addition, the presence of a gestational sac alone is not sufficient to confirm an IUP; experienced sonographers may use the double decidual sac sign, but it is recommended that less experienced sonographers visualize a yolk sac or embryo for definitive ultrasonographic confirmation of an IUP. A complex adnexal mass, tubal ring, extrauterine yolk sac or embryo, or free fluid is indicative of a probable ectopic pregnancy. The presence of free intraabdominal fluid on ultrasound with a negative urine pregnancy test is consistent with hemorrhage or a ruptured hemorrhagic ovarian cyst. Regardless of cause, intraabdominal free fluid is presumed to be blood and should be addressed expeditiously.

DIAGNOSTIC ALGORITHM

The algorithm in Fig. 30.1 is designed to focus further testing and progress to a rational provisional diagnosis. It is not unusual, however, to pursue evaluation of gynecologic and intraabdominal causes of pain in parallel, as when the initial history and physical examination do not provide clear direction. It is also possible for common diseases to manifest in uncommon ways, for more than one disease to be present, or for a positive finding not to explain the entirety of the patient's presentation. For example, patients with an abnormal urinalysis may have appendicitis, pregnant patients may also have ovarian torsion or appendicitis, and simple ovarian cysts may be asymptomatic. Tests are therefore interpreted in the context of the individual patient's presentation. With certain diseases such as endometriosis, definitive testing is not available in the ED, and the patient's history may be the most important discriminator.

After an initial history and physical examination, the pregnancy test determines the subsequent priorities, although pregnant patients are not immune to non–pregnancy-related diagnoses. For example, if a threatened abortion is most likely (ie, there is an IUP on ultrasound imaging), unilateral pain may prompt further evaluation for torsion. An empty uterus on ultrasound imaging, or any ultrasound study that cannot confirm a definite IUP, could be consistent with an ectopic pregnancy, spontaneous abortion, or very early normal pregnancy. Patients past 20 weeks' gestation will likely require observation with fetal monitoring.

Nonpregnant patients with pain that seems to be gynecologic in nature should be assessed for hemorrhage from a ruptured, hemorrhagic ovarian cyst, for ovarian torsion, and for infection, including cervicitis, endometritis, PID, salpingitis, and tubo-ovarian abscess (see Chapters 88 and 90). Although the history and physical examination often are sufficient to diagnose infection, ultrasound assessment is helpful if torsion, tubo-ovarian abscess, or ruptured hemorrhagic cyst is suspected. Ultrasound findings also may support a diagnosis of PID if evidence of salpingitis is noted or a diagnosis of a simple ruptured cyst if a characteristic ovarian appearance is combined with the presence of a small amount of free fluid. Although not as reliable as CT, ultrasound may be able to identify appendicitis.

It is difficult to differentiate some gynecologic origins of pain from intraabdominal causes (eg, right ovarian pathology from appendicitis), so ancillary testing may require an ultrasound study, CT, or both. If the cause is most likely gynecologic, an ultrasound examination of the pelvis, and subsequently the appendix, is reasonable. These studies may be followed by CT if the ultrasound findings are unremarkable and the presentation remains consistent with appendicitis or other concerning diagnoses. Pelvic US performed after CT is unlikely to yield additional useful information. When ultrasound is nondiagnostic in a pregnant patient suspected of having appendicitis, we recommend magnetic resonance imaging (MRI), which avoids the risks of progression of the disease during a prolonged observation period and obviates the need for ionizing radiation from CT. Patients whose pain does not seem to be from the reproductive tract often have urinary infections or stones, abdominal sources of pain (see Chapter 24), or musculoskeletal pathology, or may be victims of...
abuse or have depression. Vascular or neuropathic causes of pain are possible but less common.

If the available data do not make sense or conflict with the clinical gestalt, the following three steps should be considered:
1. Ensure that emergent, life-threatening diagnoses have been addressed (eg, ectopic pregnancy).
2. Reassess whether the presentation may be atypical (eg, reconsider appendicitis).
3. If emergent causes are unlikely and sufficient consideration was given to less likely disorders without uncovering a cause, address the possibility of depression or abuse. Follow-up planning for all patients is recommended.

**EMPIRICAL MANAGEMENT**

An algorithm for the management of patients with acute pelvic pain is presented in Fig. 30.2. Patients in extremis are most likely hemorrhaging, although on occasion septic shock may be the cause. Ectopic pregnancy, placental abruption, and hemorrhagic ovarian cyst may cause life-threatening hemorrhage, with no or minimal vaginal bleeding. Patients with these disorders need rapid treatment with fluid and blood products and may require surgical intervention before stabilization can be achieved. A bedside ultrasound generally will help the emergency clinician reach these presumptive diagnoses expediently. Septic shock may be a consequence of abdominal or pelvic processes and may require general surgical and gynecologic consultations, as well as admission to an intensive care setting.

We recommend early administration of analgesia for patients with significant pain, a practice that greatly improves patient comfort and the reliability of the physical examination, which is otherwise hampered by the patient’s extreme pain, tenderness, or both. For severe pain, intravenous opioids such as morphine or hydromorphone are rapid and effective, titratable, and generally considered safe in pregnancy. After critical and emergent diagnoses have been excluded, well-appearing patients for whom a definitive or reasonable provisional diagnosis is reached may be discharged with close follow-up and appropriate treatment and precautions. Pregnant patients at a stage of fetal viability (20 weeks’ gestation or as per institutional guidelines) should be referred to the obstetric service for fetal monitoring before discharge. Pregnant patients who have suffered abdominal trauma, especially those later in pregnancy, should undergo monitoring before discharge (see Chapter 182).

Acute pelvic pain in women is often from a gynecologic source, but urinary and intraabdominal sources are also common. Less frequently, the pain may arise from vascular, musculoskeletal, neurologic, or psychiatric sources.

Potentially lethal diagnoses associated with acute pelvic pain include ectopic pregnancy, ovarian cyst with significant hemorrhage, and domestic violence; highly morbid conditions presenting with acute pelvic pain include pelvic inflammatory disease and ovarian torsion.

Nearly all women of childbearing age with pelvic pain should have a pregnancy test performed, and most also require a pelvic ultrasound examination.

Ectopic pregnancy should be excluded in the pregnant patient with pelvic pain. Bedside ultrasound is an excellent test for confirming an intrauterine pregnancy (IUP); it excludes ectopic pregnancy with a high degree of certainty in patients who are not undergoing assisted reproduction.

In the nonpregnant patient, the pain of PID generally begins gradually and during menses. Ovarian cyst–associated pain is maximal at midcycle, and is usually gradual and cyclic, although it may be sudden and severe if rupture has occurred.

Pregnant patients with acute pelvic pain may also have non–pregnancy-related disorders; appendicitis, nephrolithiasis, and ovarian torsion remain in the differential diagnosis.

Many patients with acute pelvic pain require imaging as part of their assessment. If a gynecologic source is suspected, begin with an ultrasound and then progress to CT or MRI, if needed. The presence of an ovarian cyst on imaging does not necessarily explain the patient’s pain, and further evaluation may be required.

CHAPTER 30: QUESTIONS & ANSWERS

30.1. Which of the following is most true regarding the evaluation of patients with pelvic pain?
A. Ancillary testing can be limited to a urine pregnancy test in most patients.
B. Bimanual examinations have been shown to result in highly reliable findings, with substantial interobserver agreement.
C. Patients typically localize visceral pain with a high degree of accuracy.
D. Thorough history taking is adequate to exclude most life-threatening conditions.
E. None of these.

Answer: E. It is rare that any particular finding on history or physical examination is reliable enough to make or exclude a particular diagnosis conclusively in patients presenting with pelvic pain, so ancillary testing (beyond a simple pregnancy test) is commonly required in the evaluation of these patients. The bimanual examination may, at times, provide important information. Unfortunately, however, findings on pelvic examination are somewhat subjective and unreliable and may serve more to localize the process to one side or the other rather than diagnose it or even limit it to the reproductive organs. Although pelvic pain often originates from the reproductive organs, it may arise from any structures that lie adjacent to or course through the pelvis. Visceral pain afferents supplying the pelvic organs have common innervation with the appendix, ureters, and colon. Their significant overlap makes accurate localization difficult for both patient and emergency clinician.

30.2. A 26-year-old patient presents with right lower quadrant (RLQ) abdominal pain. She states her last menstrual period was 8 weeks ago. Bimanual pelvic examination reveals tenderness in the RLQ and right adnexal area. The patient’s vital signs include a regular pulse of 120 beats/min and a blood pressure of 110/68 mm Hg. Urinalysis is unremarkable, and the urine pregnancy test is positive. What is the most appropriate next test?
A. Cervical cultures
B. Complete blood count (CBC)
C. Computed tomography (CT)
D. Magnetic resonance imaging (MRI)
E. Pelvic ultrasonography

Answer: E. This follows the algorithms in Figs. 30.1 and 30.2. The most life-threatening pathology requiring urgent or emergent intervention is hemorrhage from a ruptured ectopic pregnancy. A pelvic ultrasound scan is rapid, especially when using bedside ultrasonography, and is the first step in an evaluation of a suspected ruptured ectopic pregnancy.

30.3. A 30-year-old woman presents with lower abdominal pain. She has lower abdominal, uterine, bilateral adnexal, and cervical motion tenderness on pelvic examination. She has a negative urine pregnancy test and urinalysis. What is the most appropriate next step in the patient’s management?
A. Await cervical culture results.
B. Obtain a CBC.
C. Obtain a CT scan.
D. Perform a pelvic ultrasound.
E. Treat with antibiotics.

Answer: E. The constellation of uterine tenderness, bilateral adnexal tenderness, and cervical motion tenderness is classically associated with pelvic inflammatory disease (PID), particularly when the pain onset is during or just after menstruation. The diagnosis may be made, however, without the presence of all three signs, and treatment may be initiated with only one sign in an at-risk patient, as given in the 2015 Centers for Disease Control and Prevention (CDC) guidelines.

30.4. A 35-year-old woman undergoing infertility treatment presents with severe lower left quadrant (LLQ) abdominal pain and tenderness isolated to the left adnexal area on pelvic examination. The urine pregnancy test is positive, and the urinalysis is unremarkable. Rapid bedside ultrasonography reveals an intrauterine pregnancy with a gestational age of 6 weeks, 5 days, and moderate free pelvic fluid. Which diagnoses should be further investigated at this time?
A. Ectopic pregnancy
B. Heterotopic pregnancy
C. Round ligament pain
D. Simple ovarian cyst
E. None of these

Answer: B. Women who are actively undergoing infertility treatment are at increased risk for ectopic pregnancy, heterotopic pregnancy, ovarian torsion, and ovarian hyperstimulation syndrome.
CHAPTER 31

Vaginal Bleeding

Joelle Borhart

PERSPECTIVE

Epidemiology

Abnormal uterine bleeding occurs in women of all ages and is the most common reason that women seek gynecologic care. Abnormal vaginal bleeding in nonpregnant women is rarely life-threatening, but may herald serious underlying pathology, such as cancer. Bleeding as a complication of pregnancy poses significant risk of morbidity and mortality to the fetus and mother.

Pathophysiology

Nonpregnant Patients

The mean time between menstrual periods is 28 days (±7 days), with menstruation generally lasting for 5 days. It is considered abnormal to bleed for more than 7 days. On average, 35 mL of blood is lost per menstruation; a loss of more than 80 mL is abnormal.

There has been an important change in the accepted nomenclature used to describe abnormal bleeding in nonpregnant women. Since 2011, the American Congress of Obstetricians and Gynecologists (ACOG) has recommended the PALM-COEIN classification system, which uses the all-inclusive term abnormal uterine bleeding (AUB) and divides the causes of AUB into structural and nonstructural causes. Structural causes include polyps, adenomyosis, leiomyomas, and malignancy (PALM). Nonstructural causes include coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, and not yet classified causes (COEIN). The use of the term dysfunctional uterine bleeding is no longer recommended.

Approximately 50% of cases of excessive menstruation fall under the nonstructural PALM-COEIN category of ovulatory dysfunction, which includes anovulatory bleeding. If a woman does not ovulate, there is no corpus luteum to produce progesterone, which results in estrogen being unopposed. Unopposed estrogen causes the endometrium to proliferate to the point at which it becomes unstable and begins to break down, causing irregular and unpredictable bleeding to occur. Heavy bleeding can also occur in the setting of regular ovulation (ovulatory bleeding).

Benign structural causes such as leiomyomas (fibroids) were classically thought to cause heavy bleeding by increasing endometrial surface area and disrupting the endometrial vascular supply and the ability of the uterus to contract to stop bleeding. Recent evidence has shown that aberrantly regulated growth factors may also play a role in fibroid-related bleeding. Cervical polyps, which commonly occur in multiparous women in their 40s and 50s, are friable and prone to bleeding.

Pregnant Patients

Pregnant women may experience bleeding throughout their pregnancy. In early pregnancy, ectopic pregnancy causes hemorrhage into the fallopian tube by disrupting of the blood supply to the ectopic gestational sac. Also, the size of the growing gestational sac can rupture through the tubal wall.

After the 20th week of pregnancy, vaginal bleeding can be caused by placenta previa, in which the placenta completely or partially covers the internal cervical os. As the lower part of the uterus becomes thinner during the third trimester in preparation for labor, bleeding can occur. Placental abruption causes bleeding when the placenta tears away from the uterine wall. This can occur spontaneously or secondary to abdominal trauma, with transmission of forces to the uterus. It is important to note that a large amount of concealed blood can be retained between the detached placenta and uterus, and the extent of the hemorrhage may not be fully appreciated until delivery. The most significant risk factor for abruption is a history of abruption in prior pregnancies (10-fold increased risk). An increased incidence is also seen in pregnancies complicated by hypertensive disorders, including preeclampsia, eclampsia, the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, and abnormal implantation of the placenta (eg, placenta previa, accreta, increta, percreta). Smoking and cocaine use also increase the risk for abruption.

In the immediate postpartum period (first 24 hours), bleeding is usually the result of uterine atony if the uterus fails to contract. Atony is more likely to occur with conditions that overdistend the uterus, such as a large for gestational age fetus, polyhydramnios, and multiparity. Prior history of postpartum hemorrhage, prolonged labor, induced labor, augmentation of labor with oxytocin, and instrumentation delivery also increase the risk of postpartum hemorrhage. After 24 hours postpartum, retained products of conception (POCs) is the most common cause of bleeding.

DIAGNOSTIC APPROACH

Differential Considerations

In nonpregnant women, the differential diagnosis is extensive (Box 31.1), and it is helpful to categorize the differential diagnosis by the age of the patient. In prepubescent girls, causes of vaginal bleeding include vaginitis, foreign bodies, sexual abuse, tumors, and trauma. In adolescent girls, the most common cause of abnormal vaginal bleeding is persistent anovulation due to immaturity of the hypothalamic-pituitary-ovarian axis. Underlying bleeding disorders and coagulopathies, such as von Willebrand disease, may also first present in adolescence. Sexually transmitted infections may also cause abnormal bleeding in this age group. For women in their reproductive years, structural lesions such as polyps and fibroids frequently cause abnormal bleeding. Black women are more likely to have fibroids, and they experience disproportionally more morbidity from heavy bleeding. Endocrine causes, such as polycystic ovarian syndrome, should be considered in women with signs of androgen excess—obesity, acne, hirsutism. In perimenopausal woman, anovulatory cycles become common as ovarian function declines. Endometrial atrophy is the most common cause of abnormal bleeding in postmenopausal women; however, cancer should be considered until proven otherwise.
### Differential Diagnosis of Abnormal Uterine Bleeding In Nonpregnant Females

#### STRUCTURAL CAUSES
- Polyp
- Fibroids
- Malignancy
- Hyperplasia
- Endometriosis

#### NONSTRUCTURAL CAUSES
- Coagulopathies
  - von Willebrand disease
  - Factor XI deficiency
  - Thrombocytopenia
  - Idiopathic thrombocytopenic purpura
- Endocrine
  - Polycystic ovarian syndrome
  - Hypothyroidism
  - Hyperprolactinemia
  - Adrenal hyperplasia
  - Cushing’s disease
- Systemic disease
- Kidney disease
- Liver disease
- Kidney disease
- Foreign bodies

#### Medications
- Antiepileptics
- Antipsychotics
- Anticoagulants
- Hormonal medications
- Steroids
- Intrauterine device

---

**Pivotal Findings**

#### Symptoms

Begin by eliciting the timing and duration of bleeding. Volume of blood loss is difficult to quantify because historical features, such as the frequency of changing a sanitary pad or tampon, have not been shown to predict blood loss consistently. Normal menstrual blood does not clot; therefore, the presence of clots indicates heavy bleeding. A report of dizziness, syncope, or weakness could also indicate significant blood loss. Associated symptoms such as abdominal pain, fever, vaginal discharge or odor, and postcoital bleeding could indicate a possible sexually transmitted infection or pelvic inflammatory disease. Postcoital bleeding could also indicate a cervical lesion, and occurs more commonly in pregnancy due to increased cervical blood flow. A history of trauma should be noted. Vaginal injuries can be sustained in a number of ways and range in severity from minor contusions to deep lacerations. The most common mechanism of genital injury in adult women is coitus. In pregnancy, blunt trauma, such as falls, motor vehicle accidents, and interpersonal violence, is associated with a significantly increased risk of maternal and fetal morbidity and mortality.

#### Signs

For any patient presenting with vaginal bleeding, begin by determining the patient’s hemodynamic status and performing a complete abdominal and pelvic examination. The pelvic examination may reveal the source of bleeding because masses, polyps, ulcers, foreign bodies, and evidence of trauma or inflammation may be visualized. After the 20th week of pregnancy, a pelvic examination should be deferred until after an ultrasound has been performed to exclude placenta previa as the cause of bleeding. In pregnant patients of sufficient gestational age, the fetal heart rate and fundal height should also be assessed. Fetal heart rate can be measured using the M mode on bedside ultrasound as opposed to Doppler because this is thought to transmit less acoustic energy to the fetus. Fetal cardiac activity may be measured as early as 6 weeks. Uterine size can be estimated by palpating the fundus. The uterus is palpable at the level of the umbilicus at 20 weeks. The fetal age is more than 24 weeks (ie, viable) if the uterus can be felt at least four fingerbreadths above the umbilicus. This method may be less reliable in multiple pregnancies or other conditions that might affect the distention of the uterus or abdomen, such as large fibroids, polyhydramnios, oligohydramnios, intrauterine growth restriction, and obesity. Bedside ultrasound can also be used to estimate fetal age.

---

Regardless of age, review a patient’s medication list for drugs that are known to cause abnormal bleeding (eg, antiplatelet agents, anticoagulants), antiepileptic agents (especially valproic acid), and typical and atypical antipsychotics and steroids can cause abnormal uterine bleeding.

For pregnant women with vaginal bleeding, the differential diagnosis can be refined based on whether the bleeding occurs in early or late pregnancy or postpartum. For patients with vaginal bleeding in early pregnancy (before the 20th week of gestation and prior to fetal viability), the differential diagnosis includes miscarriage, ectopic pregnancy, implantation bleeding, molar pregnancy, and ruptured corpus luteum cyst. Bleeding in early pregnancy is common, affecting up to 20% of pregnancies. Miscarriage, defined as the spontaneous termination of pregnancy before the 20th week of gestation is also common; approximately 50% of women with early bleeding will miscarry. Miscarriages are described as threatened, missed, inevitable, incomplete, or complete depending on the status of the internal cervical os and if any POCs have been passed. The most concerning diagnosis in patients with bleeding in early pregnancy is ectopic pregnancy, a pregnancy implanted outside the uterus. Ectopic pregnancy is the leading cause of first-trimester maternal death and is common among patients presenting with pain or bleeding in the first trimester of pregnancy. Risk factors for ectopic pregnancy include pelvic inflammatory disease, previous ectopic pregnancy, prior tubal surgery, use of an intrauterine device, and endometriosis. An important subgroup of patients are women undergoing assisted reproduction or in vitro fertilization (IVF). These patients are at increased risk for heterotopic pregnancies, which is a simultaneous intrauterine pregnancy (IUP) and ectopic pregnancy. Heterotopic pregnancies are rare in the general population.

Vaginal bleeding after the 20th week of pregnancy is less common, occurring in approximately 4% of pregnancies. Bleeding complications in late pregnancy generally occur in the third trimester and include placenta previa, placental abruption, and uterine rupture.
Ancillary Testing

Pregnancy status is an essential data point in the evaluation of any woman of reproductive age presenting with vaginal bleeding. Other critical laboratory tests in hemodynamically unstable patients include complete blood count, type and crossmatching of blood, coagulation studies and, if pregnant, a quantitative β-human chorionic gonadotropin (β-hCG) level determination.

Bedside ultrasound has become increasingly used in the emergency department (ED) evaluation of pregnant women with vaginal bleeding to determine whether an IUP is present. A yolk sac is the first sonographic evidence of a definite IUP and can be visualized using transvaginal ultrasound, beginning around the 5th week of pregnancy. Pregnancy of unknown location (PUL) is the term used to categorize pregnancy in a woman with a positive pregnancy test when no pregnancy can be visualized using transvaginal ultrasound. In this case, the quantitative β-hCG level has traditionally been used to determine if the level is in the discriminatory zone. The discriminatory zone is the level of β-hCG in which an IUP, if present, should be seen consistently. For transvaginal ultrasound, the discriminatory zone is generally accepted which an IUP, if present, should be seen consistently. For transvaginal ultrasound, the discriminatory zone is traditionally used to determine if the level is in the discriminatory zone. The discriminatory zone is the level of β-hCG in which an IUP, if present, should be seen consistently. For transvaginal ultrasound, the discriminatory zone is generally accepted from 1000 to 2000 IU/mL. However, the value of the discriminatory zone has recently been called into question because it is not as reliable at excluding a viable pregnancy as previously thought. Multiple studies have reported that a normal intrauterine pregnancy not visualized on ultrasound is possible if β-hCG levels are above the discriminatory zone. Therefore, caution should be used when interpreting a single β-hCG measurement because a normal gestation could potentially be disrupted. It is appropriate to repeat transvaginal ultrasound and β-hCG measurements in hemodynamically stable patients instead of initiating medical or surgical intervention for possible ectopic pregnancy based on the discriminatory zone alone. There is no β-hCG level at which an ectopic pregnancy could be completely ruled out.

Additional testing for the stable, nonpregnant ED patient, such as thyroid and other hormonal studies, is usually performed on an outpatient basis. This also includes a complete pelvic ultrasound because the results will rarely change ED management.

**Diagnostic Algorithm**

The single most important determination to make when evaluating a woman with vaginal bleeding is to determine if she is pregnant or nonpregnant (Fig. 31.1). If the patient is not known to be pregnant or immediately postpartum, a urine pregnancy test should be performed. Next, determine the age of the pregnancy in weeks. The most critical diagnoses to make in patients less than 20 weeks pregnant are ectopic and heterotopic pregnancies. Bedside ultrasound is useful to establish if an IUP is present. If the ultrasound is indeterminate, a quantitative β-hCG determination can help risk-stratify the patient further. Usually, the diagnosis will be threatened miscarriage.

For patients of more than 20 weeks gestation, the crucial diagnoses to make are placenta previa, placental abruption, uterine rupture, and arteriovenous malformation. Ultrasound should be performed before a pelvic examination in these patients.

For nonpregnant patients, the pelvic examination may reveal a cause of bleeding but, for most women in the emergency department, no cause will be identified. These patients will be diagnosed

![Fig. 31.1. Diagnostic algorithm for patient with vaginal bleeding. Ab, Abortion; β-hCG, β-human chorionic gonadotropin; coag, coagulation; DUB, dysfunctional uterine bleeding; IUP, intrauterine pregnancy; OS, cervical os; UPT, urine pregnancy test; US, ultrasonography.](image-url)
with abnormal uterine bleeding and should be referred for further gynecologic testing.

**EMPIRICAL MANAGEMENT**

Patients with hemodynamic instability unresponsive to crystalloid fluid resuscitation require blood transfusion (Fig. 31.2). For women of childbearing age, use Rh-negative blood if the Rh status of the patient is unknown. In addition to hemodynamic stabilization for severe bleeding in nonpregnant women, high-dose intravenous conjugated estrogen (Premarin) is considered first-line treatment and may be administered every 4 to 6 hours for up to 24 hours (suggested dose, 25 mg). If bleeding continues, the vagina may be packed with long continuous gauze. Alternatively, a Foley catheter may be inserted transvaginally into the uterus to tamponade bleeding. Vaginal packing and catheters may be left in place for up to 24 hours.

Treatment of stable nonpregnant patients includes nonhormonal treatments such as nonsteroidal antiinflammatory drugs (NSAIDs). Despite their varying degree of platelet activity inhibition, NSAIDs decrease blood loss by reducing endometrial prostaglandin levels and promoting vasoconstriction in the uterus. Different types of NSAIDs appear to be equally effective at reducing bleeding. Hormonal treatments such as monophasic oral contraceptive pills are also frequently used to temporize a heavy bleeding episode and are typically prescribed as a taper. Hormonal treatment is likely to be most effective for women with suspected anovulatory bleeding. Any of the monophasic pills containing less than 35 µg of ethinyl estradiol can be used; a common low-dose regimen is one pill twice daily for 5 days and then one pill daily for the remainder of the pack. Contraindications to the use of estrogen include a history of a thromboembolic event or stroke, pregnancy, active liver disease, severe uncontrolled hypertension, and women older than 35 years who smoke. High-dose, progestin-only treatment is a frequently used alternative therapy for women with contraindications to estrogen. A common regimen is medroxyprogesterone acetate (Provera) 10 mg, once daily, for 10 days (Table 31.1).

All unstable pregnant and postpartum patients should be managed in close consultation with an obstetrician. Patients with viable pregnancies may require emergency cesarean section. Unstable patients with confirmed or suspected ectopic pregnancies, heterotopic pregnancies, or previable IUPs may also require operative management. Stable patients with threatened, missed, incomplete, or inevitable miscarriages may be managed expectantly or may require dilation and evacuation or curettage. Rh status should be checked and RhoGAM treatment should be initiated in the ED for patients who are Rh-negative. The management of pregnant patients is discussed in detail in Chapters 178 to 182.

**DISPOSITION**

Most nonpregnant patients presenting to the ED with vaginal bleeding can be discharged home with timely gynecology follow-up. Adolescents with abnormal bleeding most likely have anovulatory cycles but should be evaluated for a possible underlying bleeding disorder. Perimenopausal and menopausal women with abnormal bleeding should have expedited follow-up because they are considered to have a malignancy until proven otherwise. If sexual abuse is suspected in prepubertal girls, a safe environment for the patient must be ensured before considering discharge. Any patient with significant or symptomatic bleeding should be admitted to the hospital. Pregnant patients with ruptured ectopic or heterotopic pregnancies, placenta previa, placental abruption, or uterine rupture should be admitted to the hospital. Stable patients with threatened, inevitable, incomplete, or missed miscarriage can often be managed expectantly as outpatients, with close gynecology follow-up.
### TABLE 31.1

#### Pharmacologic Treatment Regimens for Acute Abnormal Uterine Bleeding

<table>
<thead>
<tr>
<th>DRUG</th>
<th>SUGGESTED DOSE</th>
<th>CONTRAINDICATIONS AND CAUTIONS</th>
</tr>
</thead>
</table>
| Hormonal treatments                       | 25 mg IV every 4–6 h until bleeding stops, up to 24 h | • Contraindicated in patients with active or past thromboembolic disease, breast cancer, or liver disease  
• Use with caution in patients with cardiovascular or thromboembolic risk factors |
| (conjugated equine estrogen)               |                |                                       |
| Combination oral contraceptive pills      | Monophasic oral contraceptive pills containing <35 µg ethinyl estradiol recommended):  
One pill tid PO for 7 days or  
One pill bid PO for 5 days, then one pill qd until pack is finished | • Contraindicated in women >35 y who smoke  
• Contraindicated in women who have a history of deep vein thrombosis or pulmonary embolism, breast cancer, or liver disease, known thromboembolic disorders, pregnancy, ischemic heart disease, cerebrovascular disease, or uncontrolled hypertension |
| Progestin-only oral contraceptive pills (medroxyprogesterone acetate) | 20 mg tid PO for 7 days or 10 mg qd PO for 10 days | • Contraindicated in patients with active or past deep vein thrombosis or pulmonary embolism, liver disease, or breast cancer |
| NSAIDs                                    |                |                                       |
| Ibuprofen                                 | 200–400 mg tid or qid PO for 5 days | • NSAIDs contraindicated in patients with advanced renal disease  
• Use NSAIDs with caution in patients with history of GI ulcers or GI bleed |
| Mefenamic acid                            | 500 mg tid PO for 4 or 5 days or until bleeding stops |                                       |
| Naproxen                                  | 500 mg PO initially, then 250 mg tid or qid for 5 days |                                       |

*Other dosages and schedules also may be effective.

*Partial list of contraindications. The US Food and Drug Administration’s labeling contains exhaustive lists of contraindications for each of these treatments. In making treatment decisions for women with abnormal uterine bleeding, emergency clinicians should consider the risks of treatment against the risk of continued bleeding on a case by case basis.

GI, gastrointestinal; IV, intravenous; NSAIDs, nonsteroidal antiinflammatory drugs; PO, by mouth.

### KEY CONCEPTS

- Pregnancy status is the single most important determination to make when evaluating a woman with vaginal bleeding.
- There are many causes of abnormal bleeding in nonpregnant patients. Most nonpregnant patients presenting to the ED with vaginal bleeding can be safely discharged home, with timely gynecology follow-up.
- The use of the term *dysfunctional uterine bleeding* is no longer recommended; instead, use the term *abnormal uterine bleeding*.
- Hormonal and nonhormonal treatments can be initiated in the ED to temporize an acute bleeding episode in a nonpregnant patient until she can follow up with her gynecologist.
- Vaginal bleeding is common in early pregnancy. Most patients will be diagnosed with threatened miscarriage, but ectopic pregnancy should always be considered at any level of serum β-hCG.
- Vaginal bleeding after the 20th week of pregnancy is less common and is often associated with significant morbidity and mortality for the mother and fetus. These patients should be managed in close consultation with an obstetrician.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
lead to a diagnosis of threatened abortion, which is described as
considered normal. The symptoms and findings in this patient
beings during pregnancy is common but should not
31.2.
Products of conception. Missed abortion refers to retained prod-
weeks' gestation. An inevitable abortion is defined as bleeding of
depletion of some, but not all of the products of conception,
expulsion of products of conception. Patients with threatened abortion may
may not have uterine contractions. An incomplete abortion is
expulsion of some, but not all of the products of conception, which would be a complete abortion, before the completion of 20 weeks' gestation. An inevitable abortion is defined as bleeding of intrauterine origin before the completion of 20 weeks' gestation, with dilation of the cervical os but without expulsion of TFE products of conception. Missed abortion refers to retained products of conception after demise of the embryo or fetus.

31.3. A 30-year-old woman who is 26 weeks pregnant describes
a 1-hour history of painless vaginal bleeding after tripping and falling from a standing height. Her vital signs are
normal, and physical examination of the abdomen reveals
a non-tender uterus with a fundal height 1 cm above the
umbilicus. Of the following, which would be the most appropriate next step in evaluating this patient?
A. Abdominal MRI
B. Bimanual examination
C. Sterile speculum examination
D. Ultrasound

Answer: D. Painless vaginal bleeding after the 20th week of pregnancy is suggestive of placenta previa. Pelvic examination (speculum or bimanual) should be deferred until ultrasound has excluded placenta previa as the cause of bleeding.
Back pain is the most common musculoskeletal chief complaint in the emergency department (ED) and the second most common symptom-related complaint for the primary care physician (PCP). It is an enormous source of health care expenditures and lost productivity and causes more disability globally than any other condition. In the great majority of patients, back pain has a benign course; however, the goal of ED assessment is to separate the common benign causes of back pain from those that could result in significant morbidity or mortality if not promptly recognized. The key to accurate clinical decision making is performance of a thorough history and physical examination, with focus on the identification of potential markers of serious disease that will be referred to as key clinical findings (and sometimes as red flags; Box 32.1).

### Epidemiology

Over 85% of patients with acute low back pain, defined as lasting less than 6 weeks, are ultimately diagnosed with mechanical or nonspecific back pain or pain in the absence of a known specific pathology (eg, neoplastic, infectious, cauda equina syndrome, fracture, or inflammatory cause). Only about 1 in 50 ED patients with lower back pain will require hospitalization or observation. A thorough history and physical examination usually identify the roughly 2% of patients with an emergent diagnosis, including aortic dissection, abdominal aortic aneurysm (AAA), cauda equina syndrome, epidural abscess, osteomyelitis, or malignancy. Spinal carcinoma is uncommon in the general population with back pain (0.7%) but, in patients with systemic cancer, approximately 5% to 30% will have spinal metastasis, and as many as 70% of patients with a known primary tumor have spinal metastatic disease at autopsy.

The World Health Organization (WHO) defines nonspecific back pain as back pain having no known underlying identifiable pathology and no apparent relative tissue damage. Nonspecific back pain may arise in almost any patient, but has increased likelihood in patients who smoke or are obese, sedentary, or of advanced age.

Although we commonly consider disk herniation and radiculopathy together, herniation is usually asymptomatic and likely only causes symptoms of sciatica occasionally. Radiculopathy is a clinical diagnosis of nerve root irritation and compression leading to symptoms in the distribution of the affected lumbar or sacral nerve root, such as numbness, weakness, or paresthesia. The most common causes are disk herniation and foraminal stenosis caused by spondylotic degeneration.

This natural resolution of symptoms in disk disease is in contrast to spinal stenosis, which tends to persist or worsen over time. Thickening of the ligamentum flavum and other degenerative changes with age contribute to spinal stenosis. The spinal cord ends at L1 in the adult, where it gives rise to the cauda equina. Compressive lesions above the cauda equina cause upper motor neurologic signs. Compression of the cauda equina leads to lower motor neurologic findings.

Referred pain is perceived in a location other than that of the noxious stimulation. Irritation in a visceral organ frequently produces pain that may be perceived in somatic structures some distance away, such as a symptomatic AAA being felt as low back pain or ureteral colic being perceived as flank pain.

There are two proposed mechanisms for this phenomenon. The dermatomal model states that pain is usually referred to a structure that developed within the same embryonic segment or dermatome as the structure in which the pain originates. The convergence model states that pain may also be referred from the convergence of visceral and somatic pain fibers in dorsal horn neurons that project to the somatosensory cortex. It has been proposed that convergent connections from deep tissues to dorsal horn neurons may not be present initially, but are opened by nociceptive input from skeletal muscle and referral to myotomes outside the lesion due to a spread of central sensitization to adjacent spinal segments. It is for this reason that pain from intra-abdominal pathology can be referred as flank pain, back pain, or groin pain.

### Pathophysiology

Back pain may be caused by a vascular, visceral, infectious, mechanical, or rheumatologic process. Pain may originate from the spinal cord, nerve root, vertebral column, surrounding musculature, or an extraspinal origin (including thoracic, abdominal, or pelvic organs). The pathophysiology of nonradicular musculoskeletal low back pain is frequently indeterminate; possible causes may include muscle or ligament injuries, degenerative spinal disease, and disk herniation. Disk herniation occurs when the tough outer disc layer (annulus fibrosis) thins and tears, and the inner gelatinous material (nucleus pulposus) prolapses, inflames, and compresses a nerve root. This herniation may be anywhere on the continuum from asymptomatic to severely painful. Clinical symptoms are typically self-limited, with a high rate of spontaneous improvement and low likelihood of progression to a neurologic emergency. The natural history of disk herniation is that pain from pressure and nerve irritation improves as local inflammation subsides. The size of the disk protrusion may naturally decrease over time.

Although we commonly consider disk herniation and radiculopathy together, herniation is usually asymptomatic and likely only causes symptoms of sciatica occasionally. Radiculopathy is a clinical diagnosis of nerve root irritation and compression leading to symptoms in the distribution of the affected lumbar or sacral nerve root, such as numbness, weakness, or paresthesia. The most common causes are disk herniation and foraminal stenosis caused by spondylotic degeneration.

This natural resolution of symptoms in disk disease is in contrast to spinal stenosis, which tends to persist or worsen over time. Thickening of the ligamentum flavum and other degenerative changes with age contribute to spinal stenosis. The spinal cord ends at L1 in the adult, where it gives rise to the cauda equina. Compressive lesions above the cauda equina cause upper motor neurologic signs. Compression of the cauda equina leads to lower motor neurologic findings.

Referred pain is perceived in a location other than that of the noxious stimulation. Irritation in a visceral organ frequently produces pain that may be perceived in somatic structures some distance away, such as a symptomatic AAA being felt as low back pain or ureteral colic being perceived as flank pain.

There are two proposed mechanisms for this phenomenon. The dermatomal model states that pain is usually referred to a structure that developed within the same embryonic segment or dermatome as the structure in which the pain originates. The convergence model states that pain may also be referred from the convergence of visceral and somatic pain fibers in dorsal horn neurons that project to the somatosensory cortex. It has been proposed that convergent connections from deep tissues to dorsal horn neurons may not be present initially, but are opened by nociceptive input from skeletal muscle and referral to myotomes outside the lesion due to a spread of central sensitization to adjacent spinal segments. It is for this reason that pain from intra-abdominal pathology can be referred as flank pain, back pain, or groin pain.
PART I

II. DIAGNOSTIC APPROACH

Differential Considerations

The emergency clinician should evaluate for potentially life-threatening and disabling causes of back pain. These can be broken down into two main categories: (1) spinal causes, such as epidural abscess or compressive mass, spinal column injury with cord or root compression, and cauda equina syndrome; and (2) extraspinal causes, such as thoracic aortic dissection and ruptured AAA (Box 32.2).

Pivotal Findings

A careful, thorough history and physical examination are invaluable. Technologically sophisticated radiologic and laboratory studies are not a substitute for a detailed history and physical examination. This approach will help categorize patients into stable and unstable categories (Fig. 32.1). Certain findings will guide the additional evaluation for patients with neurologic deficits and more serious spinal or visceral sources (Table 32.1). The most important elements of the history, physical examination, and diagnostic testing are to answer two questions:

- Is there evidence of extraspinal or systemic disease?
- Is there evidence of neurologic compromise?

Symptoms

As with any patient who complains of pain, symptoms should be characterized by the basic historical elements of the episode, such as the intensity, onset, character, severity, location, presence of radiation, exacerbating and alleviating factors, and presence of key clinical finding signs and symptoms (see Box 32.1). Most episodes of lower back pain will resolve or significantly improve within 4 to 6 weeks; therefore, lack of significant improvement in 6 to 8 weeks is also a warning sign.

Presence of an individual key clinical finding does not necessarily correspond to a specific pathology; rather, it prompts the emergency clinician to a more serious underlying condition that may require further investigation. Many of these key clinical findings have poor or untested diagnostic accuracy and have meaning only in the context of the complete history and findings in a particular patient. Blindly allowing the presence of these individual findings to guide diagnostic treatment will lead to potentially unnecessary, misleading, and costly investigations in most patients. In one study, 80% of patients with back pain had at least one of these key clinical findings, despite a prevalence of serious disease of less than 1%. On the other hand, if there are no key clinical findings, one can be 99% confident that serious spinal disease had not been missed. Presence of multiple key clinical findings often is an indication for further investigation, which may be initiated in the ED or on an ambulatory basis, depending on the patient. In an ED population, four of the important variables associated with serious outcomes include (1) pain worse at night, (2) decreased lower extremity sensation, (3) use of anticoagulants, and (4) pain persisting despite appropriate treatment.

Different causes of acute low back pain have different distinguishing characteristics (see Table 32.1). Typical nonspecific back pain is unilateral. Pain may radiate to the buttocks or posterior thigh but not past the knee, implying muscle or ligamentous strain or disk disease without associated nerve involvement. Pain is increased with movement and is relieved by rest, and there are no complaints of numbness, weakness, or bowel or bladder dysfunction. Inflammatory back pain (spondyloarthritis) is insidious in onset, affects younger patients (<40 years), improves with exercise but not with rest, and causes pain at night, with improvement on arising. Peripheral nerve pain may be described as “pins and needles” or “burning” as opposed to nerve root pain, which is transient and very sharp, relieved with recumbent positioning and needles or “burning” as opposed to nerve root pain, which is transient and very sharp, relieved with recumbent positioning and bending.
A rapid assessment of acute low back pain includes:

- Are there abnormal vital signs? Yes/No
- Hypertension/unequal blood pressures, murmur of AI: Aortic dissection
- Evidence of neurologic deficits or focal tenderness
  - Yes/No
  - Febrile: Epidural abscess, osteomyelitis
  - Pneumonia
  - Pericarditis
  - Pyelonephritis
  - Cholecytitis
- Pain without evidence of neurologic deficits
  - Visceral: Pulmonary embolus, Renal colic
  - Biliary colic
  - Peptic ulcer disease
  - Pancreatitis
  - Prostatitis, PID
  - Musculoskeletal: Lumbosacral strain, Paraspinal muscle strain
  - Vertebral fracture (pathologic or traumatic)
  - Herniated nucleus pulposus
  - Spinal stenosis
- Afebrile: Epidural hematoma/abscess, Tumor (metastatic or primary)
  - Fracture (pathologic or traumatic)
  - Osteomyelitis
  - Herniated nucleus pulposus
  - Spinal stenosis
- Febrile: Epidural abscess, Osteomyelitis
  - Meningitis

Fig. 32.1. Rapid assessment of acute low back pain. AI, Aortic insufficiency; PID, pelvic inflammatory disease; UE, upper extremity.

Discogenic pain is typically worse with flexion, whereas pain from spondylolysis is aggravated by facet loading, which occurs in extension. Radicular pain follows a dermatomal distribution and indicates nerve root compression or irritation. Radicular pain involving the sciatic nerve (sciatica) is sharp or burning. It radiates laterally or posteriorly down the leg distal to the knee, usually to the foot or ankle, and may also be associated with numbness or weakness. Multi-nerve root pathology or the presence of bilateral symptoms is a potential indicator of a spinal mass lesion or large central disk herniation, which compresses multiple descending nerve roots within the spinal canal.

Epidual compression syndromes—spinal cord compression, cauda equina syndrome, and conus medullaris syndrome—can have a bimodal onset, acute (hours) or gradual (weeks or even months). Cauda equina syndrome usually occurs from a large lower lumbar disk herniation or by smaller prolapses in the presence of spinal stenosis. Other causes include infection, neoplasms, epidural hematoma, and trauma. There are three typical presentations: (1) acute onset of symptoms in those without a previous history of back problems; (2) acute bladder dysfunction in those with a history of low back pain and sciatica; or (3) gradual progression of symptoms in those with chronic back pain and sciatica. Epidural compression symptoms are mainly neurologic in origin and include bilateral leg pain, urinary retention with overflow incontinence, fecal incontinence or decreased rectal tone, erectile dysfunction, saddle anesthesia, and progressive and severe distal leg numbness or weakness. It is important to determine the cause of the urinary incontinence by differentiating true overflow incontinence from cases in which pain or physical limitations have prevented timely use of the bathroom.

The age of the patient is an important initial consideration. Tumors and infections appear with higher frequency in patients younger than 18 or older than 50 years. Younger patients are at increased risk of spondylolysis and spondylolisthesis. In the older patient with a first episode of back pain, or back pain distinctly different from prior episodes, consider an AAA as a potential cause. Although AAA as a cause is rare in the overall population of patients with back pain, isolated low back pain is one of the classic presentations of a contained ruptured AAA (see Chapter 76). Vigilance is required to differentiate renal colic patients from AAA in older patients because both groups may present with back pain associated with nausea, diaphoresis, or syncope, and hematuria may be present in either condition. Features significantly associated with vertebral fractures include female gender, history of osteoporosis, older age (>50, 64, or 70 years, depending on the guideline), prolonged steroid use, and substantial trauma.

Disk herniation is unusual in those younger than 18 years and is rare in the fibrotic disks of older adults. In older patients, typically those older than 60 years, spinal stenosis is suggested by lower back pain with radiculopathy that is worsened by walking and prolonged standing (back extension). This is because erect posture narrows the cross-sectional area of the central canal and neural foramina. It is relieved by forward flexion (shopping cart sign), which increases spinal canal diameter, temporarily relieving the stenosis. Spinal stenosis causes diffuse intermittent burning, cramping pain in the back, motor weakness, reflex changes, and radiating pain in the buttocks, thigh, and legs, with associated paresthesias. This symptom constellation is termed neurogenic claudication (also called psoedoclaudication) and is caused by neurologic compression, unlike vascular claudication, which is caused by arterial insufficiency, may have abnormal pulses, and is relieved by rest.

Immunocompromised patients, diabetics, intravenous drug users (IVDUs), those with recent spinal instrumentation or indwelling devices (eg, epidural catheters, spinal stimulators, vascular access) and those with a recent bacterial infection (eg, pneumonia, urinary tract infection) are at increased risk of a spinal bacterial infection. Recent gastrointestinal or genitourinary procedures may also cause a transient bacteremia, leading to an infectious cause of the patient’s back pain. A patient with current or recent IVDU and back pain should be assumed to have an abscess or vertebral osteomyelitis until proven otherwise.

Patients with cancer also represent another high-risk group. Spinal epidural metastasis can be the initial presentation of malignancy or may occur in patients with a known primary malignancy. Spinal metastases usually arise in the posterior aspect of the vertebral body, with subsequent invasion of the epidural space. The spine is the third most common site for metastatic disease, most often involving the thoracic (70%) and lumbar spines (20%). The most common metastatic diseases affecting the spine are those of the lung, breast, prostate, kidney, and thyroid, lymphoma, and multiple myeloma. Patients present with back pain that can be intermittent and often responsive to nonsteroidal antiinflammatory drugs (NSAIDs) initially, but worsens over time. History may also reveal pain at night, rest pain, pain in multiple areas of the spine, or unexplained weight loss. Sudden severe pain raises concern for a pathologic fracture.

Back pain associated with pain in other locations should prompt consideration of an extraspinal cause. Association with

<td>At-risk population with diabetes, chronic renal failure, IV drug use, alcoholism, cancer, recent spinal surgery, trauma, recent bacterial infection, bacteremia as risk factors</td>
<td>Fever (50%), back pain (75%); focal neurologic deficits are late findings (&lt;50% of patients); all three (classic triad) present in 15%; localized body tenderness along spine; rare cauda equina–like syndrome</td>
<td>CBC (elevated WBC in 60%), ESR, CRP, blood cultures useful but insensitive and nonspecific; MRI modality of choice; CT or myelography can be used; search for source of infection; <em>Staphylococcus aureus</em> common cause (70%)</td>
<td>Manifests as mass-occupying lesion compressing spinal cord; may be hematoma, malignancy, disk; often begins as focal pyogenic infection in disk; biopsy may be necessary.</td>
</tr>
<tr>
<td>Mechanical</td>
<td>Epidural compression syndrome (eg, cauda equina syndrome, neoplastic cord compression)</td>
<td>Usually history of back pain, cancer; symptoms may develop over hours; sciatica (96%), micturition dysfunction (89%), defecation dysfunction (47%)</td>
<td>Urinary retention, fecal incontinence; saddle anesthesia (81%), bilateral leg pain; lower extremity weakness with hyporeflexia</td>
<td>Evaluate postvoid residual; MRI with or without contrast; if unavailable, then CT</td>
<td>Can result in severe dysfunction; emergent condition caused by compression of lumbosacral nerve roots. Symptoms, signs depend on level.</td>
</tr>
<tr>
<td></td>
<td>Spinal fracture with cord impingement, or unstable fracture</td>
<td>Acute onset, localized pain; usually trauma history; older adults or those with chronic steroid use with osteoporosis also at risk</td>
<td>Bone tenderness, radicular, or cord compression findings</td>
<td>Plain films initially, then CT or MRI</td>
<td>Can also develop in AV malformations.</td>
</tr>
<tr>
<td></td>
<td>Epidural hematoma</td>
<td>Usually patient with coagulation disorder, hereditary or acquired (eg, anticoagulants); may occur after epidural anesthesia</td>
<td>Radicular findings (neurologic defects); neurologic pattern similar to abscess</td>
<td>MRI, CT, or myelography</td>
<td></td>
</tr>
<tr>
<td>EMERGENT</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Infectious</td>
<td>Vertebral osteomyelitis</td>
<td>At-risk group similar to that for epidural abscess; onset may be insidious; back pain, tenderness, and stiffness may precede neurologic findings by significant time period.</td>
<td>Fever, other constitutional symptoms; localized body tenderness of two adjacent vertebrae</td>
<td>CBC, blood cultures, generally low yield and nonspecific; plain films diagnostic in 80%–95%, but MRI more accurate and detailed</td>
<td>Biopsy may be necessary for diagnosis; <em>S. aureus</em> most common—start antibiotic.</td>

chest or abdominal symptoms may indicate a visceral cause, such as vascular or solid organ pathology. Unilateral flank symptoms may have a renal or retroperitoneal origin, and thoracic level pain can emanate from the chest or pleura. Because most benign back pain is tolerable, worsened with activity, and improved with rest or lying still, symptoms such as severe night pain (especially deep bony pain) and severe unremitting pain that is not relieved by rest, recumbency, or appropriate analgesic treatment are concerning for nonmusculoskeletal causes, such as malignancy or infection. Other pertinent history considerations should include past and present work history (a history of repeated loading would suggest a mechanical cause), medications (anticoagulants are associated with epidural and retroperitoneal hematomas, steroids are associated with infection and compression fractures), hematuria (nephrolithiasis, pyelonephritis, ruptured AAA), and colic (nephrolithiasis, cholelithiasis). Previous atherosclerotic or vascular disease may suggest aortic disease, and sudden-onset, severe back pain suggests a vascular cause. Direct trauma may suggest contusion, strain, or fracture. Resulting splenic, hepatic or retroperitoneal bleeding may lead to referred pain to the back.

Signs

The physical examination includes a review of the patient’s general appearance and vital signs, examination of the thorax, abdomen, and extremities, detailed examination of the back, and complete neurologic examination of the lower extremities (see Table 32.1). Lumbar spine pathology is frequently manifested in the lower extremities in the form of altered reflexes, sensation, and muscle strength (Table 32.2).

Abnormal or unstable vital signs may indicate an extraspinal cause of the back pain (eg, hypotension and tachycardia with ruptured AAA, hypertension with aortic dissection). Fever, present in approximately 50% of patients with osteomyelitis or spinal epidural abscess, indicates potential infection. The absence of fever, however, does not exclude a spinal infection.
Observe the patient’s gait and movement in the examining room because a normal gait provides important reassurance regarding the patient’s central and peripheral neurologic function.

- Does the patient move cautiously, protecting himself or herself, or move freely, appearing to be in little pain?
- Is the gait shortened, asymmetric, or antalgic?

Musculoskeletal back pain usually is mild to moderate in intensity, rarely accompanied by visceral symptoms (eg, diaphoresis, nausea, vomiting), and prompts the patient to be still. Patients presenting with extreme pain, restlessness, writhing, or visceral symptoms or signs more likely have an emergent cause. Perform cardiac and pulmonary auscultation, carry out an abdominal examination (for tenderness, bladder distention, aneurysm, or masses), and palpate for symmetry of peripheral pulses. Abdominal ultrasound can evaluate for AAA or renal colic. Examine the hips for musculoskeletal tenderness, deformity, or inflammatory focus other than the back.

The patient’s back should be fully exposed and inspected for signs of infection, trauma, or the rash of herpes zoster. The midline spinous processes should be inspected for redness, swelling, or warmth and then palpated for tenderness, which suggests fracture or infection (sensitivity, 86%; specificity, 60%). Pain during lumbar flexion suggests discogenic pain, whereas pain on lumbar extension suggests facet disease. Paraspinal muscle spasm should be noted but is not diagnostic of any particular condition.

The distal neurologic examination targets the three most common locations for disk herniation—L4, L5, and S1. A vast majority of herniated disks affect the L4-5 or L5-S1 interspaces, causing impingement on the L5 (most common) and S1 nerve roots. At each level, the emergency clinician should test corresponding muscle strength, sensation, and reflexes. When possible, motor testing of the legs is best done with the patient standing. It can be difficult to differentiate true motor weakness from apparent weakness caused by pain during motor testing. Because many muscles have innervations from multiple roots, strength may be preserved despite significant involvement of a single nerve root. Sensory fields can also have considerable overlap, so examine areas that are exclusively served by an individual nerve. True sensory loss is best tested with pinprick rather than light touch. Isolated sensory loss or the absence of a reflex is not considered to be a progressive neurologic deficit and must be correlated with the patient’s clinical picture. See Table 32.2 for nerve root levels and corresponding examination findings. Of note, ankle reflexes decrease with age, lost in nearly 30% of those older than 80 years. This loss is usually symmetric, so unilateral absence may signify pathology.

Mid and upper lumbar nerve root impingement likely has a higher prevalence than previously reported and is found with increasing frequency in older adults with spinal stenosis. Pathology at the higher lumbar spine (L1, L2, L3) will cause acute back pain, with radiation to the groin or anterior thigh, weakness with hip flexion (iliopsoas), and anterior thigh sensory changes in the corresponding dermatome. A partial knee bend while bearing weight on one leg and then the other indicates normal hip, buttock, and thigh muscle strength. There are no individual reflexes for the L1-3 lumbar levels. Those with pathology at the lower sacral levels (S2-5) will have sacral or buttck pain that radiates down the posterior leg or into the perineum and can have difficulties with penile erection (S2-4), abnormal perianal sensation (S3-5), anal wink (S2-4), rectal tone (S2-5), and bladder function (S2-4). Assessment of perianal sensation is extremely important for the diagnosis and prognosis of epidural compression syndrome. A digital rectal examination (DRE) is not a routine part of the physical examination but should be performed in those with suspicion of progressive neurologic findings (eg, epidural compression syndrome). Check the anal wink and bulbocavernous reflex and perform a Babinski test in these high-risk patients. A Babinski sign (positive plantar reflex) is extension of the great toe, with flexion and spaying of the other toes. The presence of clonus, hyperreflexia, or Babinski sign indicates an upper motor neuron lesion.

Testing for urinary retention using a postvoid residual (PVR) volume assessment by ultrasound or catheterization is highly sensitive and specific for cauda equina syndrome. Normal PVR volumes are less than 30 mL, so large PVR volumes (>100 mL) indicate a derenervated bladder and suggest significant neurologic compromise. If bladder catheterization is performed, one can test for trigone sensitivity by gently pulling on the catheter, which should produce the urge to micturate. This can help distinguish those with a true neurologic deficit from those with pain-associated retention.36

Straight leg raise (SLR) tests for disk herniation causing nerve root compression (sensitivity, 72%–97%; specificity, 11%–66%). SLR has a positive predictive value (PPV) of 67% to 89% and a negative predictive value (NPV) of 33% to 57% in patients with a high probability of having a disk herniation versus a PPV of 4% in patients with a low probability based on the absence of neurologic symptoms or sciatica. To perform this test, the patient is positioned supine, with the legs fully extended. The emergency clinician places one hand under the ankle and the other hand on the knee (to maintain leg extension). With the patient relaxed, the emergency clinician slowly lifts the patient’s leg by flexing the leg at the hip until pain is elicited or end range is reached. Test each leg separately. A positive test causes or reproduces radicular pain below the knee of the affected leg when the leg is elevated between 30 and 70 degrees. Care should be taken that the patient is not actively helping in lifting the leg and that the knee remains straight throughout the examination.

A further positive finding occurs if radicular symptoms are elicited when the leg is then lowered until pain is eased and the ipsilateral ankle is dorsiflexed (Braggad’s sign). Pain at less than 30 degrees, more than 70 degrees, or with reproduction of pain only in the back, hamstring, or buttock region, does not constitute a positive test result. Pain referred to the affected leg when the opposite asymptomatic leg is tested, called a positive crossed SLR, is highly indicative of nerve root irritation from a herniated disk (specificity, 85%–100%; sensitivity, 29%).20 In cases where the patient is reluctant or unwilling to lie supine for SLR testing, the seated SLR or slump test should be attempted. The patient sits at the edge of the examination table and slumps forward while flexing the neck and trunk. This is followed by knee extension and ankle dorsiflexion. A positive test reproduces radicular pain.

Waddell’s examination findings can aid in distinguishing between true pathologic back pain and nonorganic back pain; it can be remembered by the mnemonic DORST—distraction, overreaction, regional disturbances, simulation tests, tenderness. Waddell’s signs, especially if three or more are present, correlate with malingering and functional complaints (physical findings without anatomic cause). Superficial, nonanatomic, or variable tenderness during the physical examination suggests a nonorganic cause. Provocative maneuvers such as axial loading of the head or passive rotation of the shoulders and pelvis in the same plane should not elicit low back pain. There may be a discrepancy between the symptoms reported during the supine and seated SLR tests. The seated version of the test, sometimes termed the distracted SLR, can be performed while distracting the patient or appearing to focus on the knee. Furthermore, radicular pain elicited at a leg elevation of less than 30 degrees is suspicious because the nerve root and surrounding dura do not move in the neural foramen until an elevation of more than 30 degrees is reached. Sensory and motor findings suggestive of a nonorganic cause include stocking, glove, or nondermatomal sensory loss or weakness that can be characterized as “give-way,” jerky, or cogwheel
weakness. Finally, gross overreaction is suggested by exaggerated, inconsistent, painful responses to a stimulus. These signs can be used in the evaluation of select patients and are merely a component of a comprehensive physical examination. They should never be used independently because they lack the sensitivity and specificity to rule out true organic pathology.

ANCILLARY TESTING

Ancillary testing is not indicated in the absence of concerning findings, and routine (nonemergent) use of computed tomography (CT), magnetic resonance imaging (MRI), or laboratory testing should be discouraged. Blind diagnostic testing may lead to false-positive results and further unnecessary evaluations and interventions.

Laboratory Tests

Laboratory testing, consisting of the determination of the white blood cell count (WBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) level is indicated for clinical suspicion of infection or malignancy, new-onset back pain with a history of malignancy, or multiple risk factors for cancer. In cases of spinal infection, the sensitivity of an elevated WBC count is poor (35%–61%), but the ESR (76%–95%) and CRP (82%–98%) are more sensitive and may help guide further evaluation or consideration of other entities. Incorporation of ESR and CRP values into an ED decision guideline may improve diagnostic delays and help distinguish patients in whom MRI may be performed on a nonemergent basis. Infection is very unlikely in patients with an ESR less than 20 mm/h. An elevated ESR (>20 mm/h) is nonspecific for infection, however, and also may indicate occult malignancy (sensitivity, 78%; specificity, 67%). Urinalysis (UA) may be useful in suspected cases of renal disease with referred back pain (eg, nephrolithiasis, pyelonephritis, urinary tract infection). Blood cultures may be sent when there is a significant concern for an infectious cause, such as an epidural abscess, but this will not affect immediate decision making.

Imaging

Imaging, like laboratory testing, is not indicated in the absence of concerns for malignancy, fracture, infection, or epidural compression syndrome. Although the added diagnostic value of modern neuroimaging is significant, unnecessary imaging only serves to increase the cost of the visit and length of stay and subject the patient to unnecessary radiation. Multiple evidence-based clinical practice guidelines have recommended avoiding routine spinal imaging for nontraumatic acute lower back pain in the absence of severe or progressive neurologic deficits or signs and symptoms that suggest a serious underlying condition. Although patient satisfaction is reportedly higher when imaging is performed, this is likely because the negative imaging provided a reassuring explanation for the patient, one that could, instead, have been provided by a thoughtful reassuring discussion by the emergency clinician. Early imaging is not useful and does not affect outcomes for pain, function, quality of life, or overall patient-related improvement. Across all age ranges, including older adults, imaging does not change the management of uncomplicated mechanical low back pain compared with usual care being provided without routine imaging. Despite this, a substantial portion of ED patients with lower back pain undergo nonindicated imaging. Plain films are rarely of use in the evaluation of nontraumatic back pain unless pathologic fracture is suspected. Most patients who require imaging will undergo CT or MRI. Plain films are indicated for new onset of lower back pain in a patient with a history of cancer, strong clinical suspicion for cancer, risk factors for pathologic vertebral fracture, and trauma. Anteroposterior (AP) and lateral films provide reasonable detail in showing fractures, particularly in the lumbar spine. Additional views are only indicated if spondylolisthesis or spondyloarthrosis is suspected. If evidence of neurologic emergency exists, bypass plain films and proceed directly to CT or MRI. For example, only a small minority of patients with malignant spinal cord compression will have the level of compression correctly identified on plain radiographs. In general, CT provides superior imaging of bone and only moderate detail of soft tissue, whereas MRI gives excellent detail of soft tissue and only moderate detail of bone. CT is increasingly used as a primary screening modality for moderate to severe spine trauma because it is superior to plain film for the detection of vertebral fractures and other bony pathology, especially fractures involving posterior spine structures, bone fragments within the spinal canal, or spinal malalignment. CT provides reasonable contrast resolution and can identify root compressive lesions, such as disk herniations, in the vast majority of cases. CT with myelography (or with intravenous [IV] gadolinium) may be used if there is concern for epidural abscess, epidural compression, or vertebral osteomyelitis in patients who are otherwise unable to have a MRI. CT cannot identify intrathecal pathology and is less sensitive than MRI in the detection of early inflammatory or infectious processes, neoplasm, or paraspinal soft tissue lesions.

With the exception of the evaluation of acute trauma, MRI will identify almost all pathologic states that could benefit from surgical management. MRI is the modality of choice for evaluation of spinal infectious lesions (sensitivity and specificity > 90%), malignancy (sensitivity, 90%; specificity, 95%), disk herniation, and epidural compression syndrome (sensitivity and specificity > 90%). MRI in the ED is indicated for those patients with lower back pain in whom spinal infection, cauda equina syndrome, and/or severe or progressive neurologic deficits are suspected. Without these clinical indications, MRI does not improve clinical outcomes (eg, pain, daily function, health status) and may actually worsen them, resulting in increased rates of subsequent interventions (eg, lumbosacral injections, back surgery) and increased health care expenditures.

MRI is too sensitive and not specific enough to screen for other presentations of back pain in the ED and has no role in the evaluation of chronic lower back pain without strong clinical consideration of emergent pathologic causes. In patients with chronic, nonradicular pain, MRI findings are not related to disability or pain intensity. Disk disease is a component of normal aging and is a very nonspecific finding. In fact, one in four asymptomatic persons younger than 60 years and one in three older than 60 years will have MRI findings of a herniated disk. Over 50% of asymptomatic patients are identified as having a bulging disk on MRI. Furthermore MRI studies have shown that almost two-thirds of herniated disks regress or resolve over 6 months. Thus, imaging can reveal pathoanatomic abnormalities that have little or no correlation with patient symptoms.

DIAGNOSTIC ALGORITHM

Critical Diagnoses

Following the history and physical examination, patients with acute low back pain can be divided into three main categories: (1) those with extraspinal causes (chest, abdominal, or retroperitoneal); (2) those with critical or emergent spinal pathology (eg, from tumor, infection, or epidural compression syndrome); and (3) those with nonspecific lower back pain, sciatica, or spinal stenosis. (see Box 32.2) The first priority is to rule out nonspinal pathology, such as an AAA. The next step is to exclude the presence of serious spinal pathology, such as epidural compression syndrome or abscess. The final priority is to decide whether the
patient has musculoskeletal or nerve root pain. In the absence of radicular pain, the pain is classified as nonspecific low back pain.

Most patients seen in the ED will have nonspecific low back pain, and no laboratory testing or imaging is indicated. A smaller group of patients will have radiculopathy or spinal stenosis. In the absence of key clinical findings or progressive neurologic symptoms, treatment will generally mirror that of nonspecific low back pain, and MRI can be delayed for 4 to 6 weeks and coordinated by the PCP if they are candidates for surgery or interventional pain management (eg, epidural steroid injections). Most patients with sciatica recover without surgery.

Following the history and physical examination, the minority of patients who have multiple key clinical findings or a moderate to high probability of a critical or emergent condition will require further urgent evaluation and management aimed at identifying and treating the underlying cause. This care is started in the ED and usually consists of an MRI evaluation. The degree of neurologic impairment, duration, and rate of worsening dictate whether these tests are performed on an urgent or emergent basis. If the motor loss in a muscle segment is rapidly progressive or 3/5 or less, MRI and spine surgery consultation should be undertaken emergently. If motor loss is subacute, stable, and with 4/5 strength, it is possible to wait 1 or 2 days for imaging, with surgical follow-up soon after. This should be arranged with the PCP, radiologist, and surgeon. The patient is instructed to return immediately if worsening weakness occurs.

Spinal epidural abscess remains a very challenging diagnosis to make. Almost 50% of patients are initially misdiagnosed and average two ED visits before admission. Do not rely on the classic triad of fever, back pain, and neurologic deficits because all three components are present only 15% of the time and fever is only present in 50% to 66% of patients at presentation. ESR and CRP values may help in risk stratification. Perform MRI when a moderate to high pretest probability exists (eg, use of IV drugs with new back pain and unexplained fever), regardless of a normal WBC count and neurologic examination and the absence of fever.18 Preoperative neurologic function is a good predictor of final outcome. Those with few to no risk factors, normal WBC, ESR, CRP, and plain films, and a normal neurologic examination can be managed with close follow-up and appropriate discharge instructions.

Like spinal epidural abscess, cord compression (eg, cauda equina syndrome) is another critical condition in which delayed diagnosis is common, and neurologic function at the time of diagnosis is the primary determinant of the ultimate outcome. Unfortunately, no constellation of symptoms or examination findings is 100% sensitive. No single symptom predicts the radiographic finding of cauda equina syndrome with an accuracy greater than 65%.34,35 The probability of significant epidural spinal compression without urinary retention is highly unlikely, although it should be noted that postvoid residual volume can be increased in patients on opioid analgesics. MRI of the lumbosacral spine should be ordered from the ED if there is moderate to high suspicion. Contrast enhancement is not necessary in most cases, but when an infiltrative cause is suspected, such as from infection or metastasis, contrast may be useful. The MRI should include the entire spine to evaluate for falsely localizing sensory levels because clinically silent multilevel involvement is common, and there is a 10% risk of distant asymptomatic metastasis, which may affect subsequent treatment (eg, cervical lesion causing a thoracic sensory level). Fewer than 25% of patients with malignant spinal cord compression have a sensory level within three vertebrae of the true compression level, as demonstrated on an MRI scan. Early initiation of glucocorticoids in consultation with the treating spinal surgeon should follow when the diagnosis is suspected, rather than waiting hours for confirmatory testing. Neoplastic epidural spinal cord compression is a true emergency and requires prompt diagnosis and treatment for the best possible patient outcome. ED management includes early MRI, pain control, and high-dose corticosteroids, with specialty consultation for radiation therapy and/or surgical decompression.

A systematic approach to the patient with cancer and back pain is accomplished by categorizing patients into two groups based on signs and symptoms:

1. Patients with sudden or rapid change in their back pain, development of new or progressive signs or symptoms suspicious for epidural compression (eg, bowel or bladder incontinence, weakness, loss of reflexes, multiroot findings), especially the development of bilateral severe sciatica. These patients are at high risk for rapid deterioration and should be evaluated and treated as previously discussed for possible emergent epidural compression syndrome in the ED.

2. Patients with back pain but without changes in neurologic status should have plain films and ESR and CRP determinations in the ED. If these are abnormal, or any change in neurologic status occurs, obtain an MRI scan within 24 hours (inpatient or outpatient).

If there is any bony pathology, advanced imaging with MRI or CT is indicated on an outpatient basis within the next several days. If plain films are normal, further evaluation is not emergent. Patients must be closely followed by their PCP for improvement and lack of progressive symptoms. A follow-up appointment should occur within 1 week.

Finally, some patients without known cancer have key clinical findings suggestive of malignancy, such as unexplained weight loss or back pain that is worse at night. As previously discussed, these patients require further risk stratification with plain radiographs and laboratory testing, including a WBC count, ESR, and CRP.18 With normal test results, these patients can be referred to their PCP for further evaluation. With abnormal diagnostic results, such as a bone lesion on plain film or an extremely elevated ESR, urgent MRI should be performed on an outpatient basis within the next week.

Empirical Management

In general, the recommended role of the emergency clinician in the management of acute lower back pain is to identify whether significant pathology is present, and establish a correct diagnosis while avoiding excessive investigation. Subsequent goals include initiating appropriate treatment, providing analgesia, and educating the patient. The initial empirical management of acute back pain depends on the presenting vital signs and the patient’s overall appearance. Figure 32.2 details the specific management considerations for treatment.

Show support by acknowledging the patient’s pain and providing reassurance that back pain is very common, the pain does not indicate ongoing harm or serious pathology, and most patients eventually experience spontaneous improvement. Care should be taken to avoid negative or confusing messages. An example of this would be avoiding language that might frighten the medically naive patient (eg, ruptured disk) and imply a serious abnormality when none exists.31,32 Provide a full explanation of the diagnosis, evaluation, treatment plan, and expected time course for recovery in terms that the patient understands. Patients should be educated about why they are not undergoing laboratory or radiographic studies and should be reassured of the likely benign course of the pain. Most patients can be convinced by education and an explanation of radiation dosing and associated deleterious effects. This approach will help avoid misperceptions of substandard care or subsequent unnecessary return visits within 48 hours when symptoms are still present. For some patients, chronic, recurrent back pain is a long-term issue, and they may visit the ED during an acute exacerbation. These patients still require a thorough
examination and review of key clinical findings to risk-stratify them better and guide ED evaluation. Labelling these patients without performing a thorough investigation can have dangerous consequences. For example, cauda equina syndrome is often seen in those with a prior history of back pain or sciatica.

One of the most important goals of treatment is to provide an acceptable level of analgesia while the underlying condition resolves, or ameliorate the suffering of those patients who await definitive therapy. Emergency clinicians also should be alert to racial bias in treatment of back pain.33 Despite numerous studies and recommendations, few if any treatments have been proven effective for the management of low back pain. Patients’ expectations are known to influence the outcome of treatment, and this process can begin in the ED. Advice and information about back pain, carefully selected and presented, can have a positive effect on patients’ beliefs and clinical outcomes.32 Setting a goal that a pain-free expectation is less realistic than pain improvement may be beneficial. Avoid making unnecessary presumptive diagnoses, and avoid the medicalization of benign conditions by ordering unnecessary tests. This behavior, coupled with the overprescription of analgesics, particularly opioids, fosters a belief on the part of the patient of the existence of serious pathology for an otherwise benign condition.

Nonpharmacologic analgesia can include the use of heat or cold externally applied to the lower back. There is better evidence for the benefits of heat than ice for the treatment of lower back pain. First-line pharmacologic therapy includes nonopioid analgesics (eg, acetaminophen, NSAIDs). Some studies have called into question the efficacy of acetaminophen for acute lower back pain. Despite claims to the contrary, there is no convincing evidence for the benefit of acetaminophen to NSAID therapy. Parenteral NSAID analgesia is rarely indicated and is no more effective than an equivalent dose of an oral NSAID. Lidocaine transdermal patches (Lidoderm) are a safe, nonsedating, effective treatment option for acute and subacute back pain. There is little to no benefit of adding high-dose acetaminophen to NSAID therapy. Parenteral NSAID analgesia is rarely indicated and is no more effective than an equivalent dose of an oral NSAID. Lidocaine transdermal patches (Lidoderm) are a safe, nonsedating, effective treatment option for acute and subacute back pain.

Despite claims to the contrary, there is no convincing evidence for the benefit of so-called muscle relaxants, such as cyclobenzaprine and carisoprodol, for acute back pain, and we do not recommend their use.37 These medications have a high incidence of significant side effects, such as anticholinergic effects, dizziness, and sedation, thereby limiting their use. When simple analgesia is not sufficient, despite a reasonable trial with proper dosing, and the patient has prominent symptoms of sleep disturbance and anxiety related to the pain, a benzodiazepine may be prescribed.

Fig. 32.2. Management of acute low back pain. AAA, Abdominal aortic aneurysm; ADLs, activities of daily living; ASAP, as soon as possible; CBC, complete blood count; CRP, C-reactive protein; CT, computed tomography; ECG, electrocardiogram; echo, echocardiogram; ED, emergency department; ESR, erythrocyte sedimentation rate; exam, examination; H&P, history and physical examination; IVDU, intravenous drug use; MRI, magnetic resonance imaging; neuro, neurologic; NSAIDs, nonsteroidal antiinflammatory drugs.
as an adjunct to nonopioid analgesia. Their effect, if any, likely is based on their anxiolytic and sedative properties, which may promote sleep and synergize pain relief. Sleep quality is related to subsequent lower back pain intensity,39 so benzodiazepines may be beneficial, with limited side effects, when taken at bedtime. There is no clear benefit of oral glucocorticoids prescribed in the ED in regard to low back pain (with or without sciatica), activity level, or ability to return to work.39

If the pain is severe, IV opioids such as morphine or hydromorphone are the preferred analgesic and should be given in a titrated fashion. However, opioids should be considered a second-line alternative and are best used for those experiencing severe acute back pain with inadequate control with nonopioid analgesics.39 When administering opioids, frequently reassess the patients until an adequate response is reached, and then transition to oral agents in preparation for discharge.

Despite back pain being the most common indication for opioid prescription in an ED population, routine use of opioids for acute or chronic back pain is not recommended.19 Also, although opioids are effective for relieving pain, they do not improve functional status. When prescribed, opioids should be combined with NSAIDs, taken on a fixed dosing schedule at the lowest dose possible, and taken only for a limited, clearly defined period (eg, <1 week). The emergency clinician should always consider the known side effects of opioids (eg, constipation, confusion, sedation), especially in older adults, in addition to the individual patient’s risk for opioid misuse, abuse, or diversion.

In summary, for patients with mild pain, NSAIDs are the first-line medication unless contraindicated, in which case acetaminophen is preferred. For patients with severe pain, add a low-dose opioid on a fixed dosing schedule for 2 to 3 days. These patients may also benefit from the addition of a benzodiazepine if the pain, sleep disturbance, and anxiety remain prominent.

With chronic back pain, however, opioid efficacy is less clear and should be carefully considered in the absence of a new acute condition. In the chronic back pain population, prescription opioid abuse is epidemic, and aberrant medication taking occurs in up to 25% of cases. Compared to placebo, opioids do improve pain and function in the short-term for chronic lower back pain.42 However, although opioids and NSAIDs are effective for chronic lower back pain, opioids do not confer a greater benefit with regard to pain or disability.43 For such patients, NSAIDs are indicated as first-line treatment, and opioids should be considered as an adjunct for short-term pain relief only and should be avoided whenever possible.44,45 Opioids should not be prescribed to patients with chronic musculoskeletal pain in the ED (see Chapter 3). They should be referred to a pain management center, where epidural glucocorticoid injections and other potential treatments may be provided.

The disposition of patients with back pain depends on their diagnosis. Patients with a life-threatening or disabling cause require emergent treatment, consultation, and admission. Patients with acute cord compression from a fracture, disk protrusion, abscess, or hematoma require urgent surgical evaluation initiated in the ED. Patients with cancer and intractable bone pain may also require admission for pain control. Patients with epidural abscess will also require administration of IV antibiotics and likely surgical consultation. Almost all patients with nonspecific lower back pain can be discharged from the ED with PCP follow-up. In rare circumstances, severe ongoing pain, despite treatment, or inadequate support at home may necessitate admission to the hospital or the ED observation unit.

Although patients should avoid vigorous exercise and provocative activities, complete rest should be avoided. Bed rest has been proven to be deleterious to successful recuperation from back pain, leading to less functional recovery and slightly increased pain than for those advised to remain ambulatory. Remaining active will also help with muscle spasm and atrophy. However, patients with severe pain may be able to do little beyond navigating between the bedroom, bathroom, and kitchen. The perception of activity as a trigger may predispose patients to experience additional disability. It should be made clear that ongoing pain does not imply ongoing harm. Recommend continuing daily activities and gradually increasing specific exercises, as tolerated. Clarify that back pain does not need to be totally alleviated before the patient can return to work. Returning to work should be based on consideration of the actual work duties of the patient. Those with jobs involving heavy manual labor may benefit from time away from work if no light duty options are available, and ED work notes should make this distinction clear. All patients with back pain evaluated in the ED who are not admitted should be given clear discharge instructions, with unambiguous indications to return to the ED immediately with symptoms such as new or progressive leg weakness, bowel or bladder dysfunction, or saddle anesthesia.

KEY CONCEPTS

- Acute low back pain is a common, costly, recurring, and painful condition that often has no recognizable or dangerous cause. Most low back pain is nonspecific and improves without laboratory evaluation or imaging.
- The vast majority of patients can be properly managed by their PCP and do not require ED consultation or specialty referral.
- A focused history should be elicited from patients with lower back pain, with the goal of uncovering high-risk features that would predispose the patient to an emergent or life-threatening situation. The physical examination should focus on the lower extremity neurologic examination, including testing of strength, sensation, and reflexes.
- Imaging and laboratory studies are rarely indicated following the history and physical examination and are only indicated when there is evidence of neurologic deficit or multiple key clinical findings suggesting a dangerous or systemic pathologic cause.
- Adherence to published guidelines will decrease the use of improper laboratory studies and imaging, thereby lowering costs, reducing ED throughput, and improving overall patient care.
- MRI in the ED should only be ordered when there is strong consideration of a serious or progressive neurologic lesion or spinal infection. When a critical or emergent diagnosis is strongly suspected, MRI and spine surgery consultation should be undertaken emergently.
- Patients who have low back pain emergencies are generally classified in two five groups: (1) past medical history of malignancy and new back pain, with neurologic findings; (2) back pain and symptoms of epidural compression syndrome; (3) back pain with symptoms suggesting an infectious cause; (4) back pain with gross muscle weakness or paralysis; and (5) back pain and bilateral or multiple nerve root involvement.

ACKNOWLEDGMENTS

The author would like to thank Brian Mahoney, who wrote the prior edition of this chapter, and Roy Hatch and Natalie Davis for their invaluable assistance in preparing this chapter.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
REFERENCES

47. C. 50%

48. D. 66%

49. E. 90%

Answer: D. Serial magnetic resonance imaging (MRI) studies have shown that 66% of herniated disks regress or resolve over 6 months. This high percentage argues for early conservative therapy and argues against early MRI or computed tomography (CT) imaging.

50. 32.3. A 35-year-old man presents with severe back pain that radiates down his right leg. He reports that while lifting a heavy box at work 2 weeks ago, he felt a “pop” in his lower back. He has not been able to return to work since the injury occurred. The patient spoke with his lawyer and was told to come directly to the emergency department to get an MRI. He denies having any other symptoms and reports no significant past medical history. During the
physical examination, the patient is asked to lie on his back, with his knees extended. His right leg is elevated and, at 50 degrees, he reports severe pain running down the lateral aspect of his right leg to his foot. The patient is then asked to sit with his knees flexed and legs hanging over the side of the bed. His legs are passively extended, with no production of pain. The remainder of the physical examination is normal. What is the most appropriate next step in managing this patient?
A. CT of the lumbar spine  
B. Discharge home  
C. Emergent neurosurgical consultation  
D. MRI of the lumbar spine  
E. Radiography of the lumbar spine

Answer: B. Several aspects of this scenario point to malingering. The most convincing relates to the physical examination findings. The straight leg raise (SLR) is the classic test for sciatic nerve root irritation. The absence of a positive result generally rules out nerve root irritation. To perform the SLR, the patient is positioned supine, knee extended, and leg elevated until pain is elicited. A positive result is pain radiating down the leg below the knee in a dermatomal distribution when the leg is elevated between 30 and 70 degrees. In a patient who may be malingering, the SLR can be performed with the patient sitting on the side of the bed with knees flexed. Passively straightening the legs in this position should produce equally positive results if true nerve root irritation exists.

32.4. Disk herniation with involvement of the L5 nerve root will present with which of the following findings?
A. Decreased or absent ankle jerk  
B. Decreased patellar reflex  
C. Diminished sensation of the lateral small toe  
D. Impaired plantar flexion  
E. Weakness with extension of the great toe

Answer: E. Involvement of the L5 nerve root presents with weakness, with extension of the great toe, decreased sensation in the first web space, and normal reflexes. An S1 radiculopathy is characterized by diminished sensation of the lateral small toe, impaired plantar flexion, and decreased or absent ankle jerk. The patellar reflex is associated with L2-4.

32.5. A history of intravenous (IV) drug use increases the risk for which of the following causes of acute back pain?
A. Abdominal aortic aneurysm  
B. Epidural hematoma  
C. Malignancy  
D. Transverse myelitis  
E. Vertebral osteomyelitis

Answer: E. Vertebral osteomyelitis and spinal epidural abscess are diagnosed most frequently in an at-risk population that includes patients with a history of diabetes, chronic renal failure, IV drug use, alcoholism, cancer, AND recent surgery or trauma.

32.6. Plain films have the highest utility in diagnosing which of the following?
A. Abdominal aortic aneurysm  
B. Epidural hematoma  
C. Spinal stenosis  
D. Transverse myelitis  
E. Vertebral osteomyelitis

Answer: E. Plain films are diagnostic in 80% to 95% of cases of vertebral osteomyelitis. There is limited usefulness with any of the other conditions listed.

32.7. Spinal epidural abscess is most commonly caused by which of the following pathogens?
A. Mycobacterium tuberculosis  
B. Pseudomonas aeruginosa  
C. Staphylococcus aureus  
D. Staphylococcus epidermidis  
E. Streptococcus pyogenes

Answer: C. S. aureus causes 70% of spinal epidural abscesses.
In 2012, there were almost 33,000 deaths by firearms. The economic cost of traumatic injuries and death is estimated in the hundreds of trillions of dollars, which includes medical costs and lost productivity. Between 2000 and 2012, primarily because of increased seat belt use, the motor vehicle fatality rate declined almost by one-third, to fewer than 11 deaths/100,000 population.

**ANATOMY AND PHYSIOLOGY**

In contrast to penetrating trauma from knife wounds, in which injuries can be expected to occur only along the track of the weapon, injuries inflicted by gunshot wounds depend on several factors. The amount of tissue damage is related to the kinetic energy of the bullet, which is a factor of the bullet weight (caliber) and velocity. Gunshot wounds cause trauma to the surrounding tissue by direct laceration, crush injury, shock waves, and cavitation—the displacement of tissue forward and radially. Because of these dynamic forces, high-velocity weapons, such as rifles, cause more widespread injuries than low-velocity weapons, such as handguns. Similar to knives, handgun bullets and shotgun pellets (from long range) generally cause injury based on direct laceration and crush generated by the missile along its track. Shotgun wounds from close range are characterized by massive tissue injury.

Injury patterns can differ significantly between adults and children subjected to similar mechanisms of trauma. Pediatric trauma is discussed in Chapter 165. Older patients commonly sustain extremity, craniofacial, and closed head injuries. Most of these occur as the result of a fall or MVC. Unintentional injury was the fourth leading cause of death in 2013. Older trauma patients typically have comorbid illnesses, may be taking relevant medications (especially anticoagulants) and also have normal, age-related changes in organ system function. These factors can increase susceptibility to injury, morbidity, and mortality.

**Epidemiology**

Motor vehicle collisions (MVCs) are the leading cause of trauma-related mortality in people aged 1 to 44 years. Firearm deaths are a significant concern unique to the United States (see Chapter e2). In 2012, there were almost 33,000 deaths by firearms. The economic cost of traumatic injuries and death is estimated in the hundreds of trillions of dollars, which includes medical costs and lost productivity. Between 2000 and 2012, primarily because of increased seat belt use, the motor vehicle fatality rate declined almost by one-third, to fewer than 11 deaths/100,000 population.

**Pathophysiology**

In blunt trauma victims, the mechanism of injury can be associated with particular injury patterns. These are listed in Table 33.1. Knowledge of these associations can help the provider evaluate for injuries that may not be readily identified on the initial examination.

**CLINICAL FEATURES**

**Primary Survey**

The primary survey should be performed in a standardized fashion immediately after the patient arrives in the emergency department (ED). The goal of the primary survey is to diagnose critical, life-threatening injuries rapidly and begin treatment at the time of diagnosis. Figs. 33.1, 33.2, and 33.3 show the recommended algorithms for the evaluation of airway, breathing, and circulation. Fig. 33.4 describes special considerations between blunt and penetrating mechanisms that should be considered during the primary survey.

Traumatic causes of a compromised airway, such as by a neck or maxillofacial injury, are typically easily recognized. In the absence of obvious direct trauma involving the airway, airway management decisions are based on the overall patient condition and anticipated clinical course (see Chapter 1).

Inadequate ventilation, which may lead to respiratory acidosis, can be noted by the rate and quality of respirations. Pulse oximetry will detect inadequate oxygenation, which may manifest clinically as agitation and restlessness. Assessment for injuries that may compromise oxygenation, ventilation, or both requires careful inspection and auscultation of the chest. Signs of such compromising injury include increased work of breathing, tachypnea, penetrating wounds, subcutaneous emphysema, chest wall instability, flail segments, tracheal deviation, and distended neck veins. See Fig. 33.2.

Assessment of hemodynamic and circulatory status (see Fig. 33.3) follows evaluation of the airway and ventilation. Clinical indicators of adequate perfusion include normal mental status, skin color and temperature, heart rate, blood pressure, and capillary refill. However, a normal finding for any single sign does not rule out significant hemorrhage or even shock. Mental status changes associated with hypoperfusion can include anxiety, agitation, and depressed consciousness. Cool pale skin or extremities...

with delayed capillary refill suggest inadequate perfusion and shock. A normal heart rate, blood pressure, or both can be present, despite significant hemorrhage. Conversely, tachycardia may be seen without significant volume loss.

Traditionally, direct pressure to external bleeding sites has been advocated, and the use of tourniquets has been discouraged. The use of direct pressure on the bleeding site remains first-line therapy, but there is good evidence to support the early use of tourniquets for massive extremity hemorrhage that is not otherwise easily controlled. Similarly, studies of newer hemostatic agents have shown potential application in combat and out-of-hospital settings.

Early intravenous (IV) access is required in the assessment of circulation. We recommend two large-bore (14- or 16-gauge) IV catheters. Routine IV access may be difficult or unobtainable in certain cases. Intraosseous vascular access can be obtained rapidly in pediatric and adult patients and allows the safe infusion of large amounts of fluid or blood products. Compact, battery-operated intraosseous drills are commonly available, and their use has been well established. Ultrasound-guided peripheral venous access by nurses and emergency clinicians should be considered in patients when blind peripheral attempts are unsuccessful. Central venous access may also be indicated in the appropriate clinical scenario or based on the emergency clinician’s discretion. The use of ultrasound (US) has been shown to increase successful vein cannulation and decrease complications in the placement of central venous lines in pediatric patients and adults. Central venous pressure measurements may be used to direct resuscitative efforts, but should not delay definitive care. Real-time US of the vena cava can be performed much more quickly by assessing its size and the degree of respiratory variation to determine adequacy of resuscitation. We recommend that an extended, focused, abdominal sonography in trauma (eFAST) examination be performed on all patients at the transition point from the primary to secondary survey.

Secondary Survey

The goals of the secondary survey are to obtain pertinent historical data about the patient and injury and identify and manage all significant injuries by performing a systematic, complete examination. An AMPLE (allergies, medications, past medical history, last meal, environments and events) history should be obtained. Trauma is a dynamic process, requiring frequent reassessment of the patient’s level of consciousness, airway, circulatory, and pain status throughout the ED phase of management. If deterioration occurs, a complete reevaluation of the primary survey should be initiated. Features of the secondary survey, with critical and emergent diagnoses, are listed in Table 33.2. Concurrently with the primary and secondary survey, oxygenation is enhanced as necessary, appropriate IV access is established, and volume resuscitation (as needed) commences. On completion of the secondary survey, laboratory and more extensive radiographic evaluations commence.

Differential Diagnoses

The differential diagnosis of injuries to the airway or chest that might compromise the airway or breathing is finite. In contrast, circulation problems have a variety of potential causes. Figs. 33.2 and 33.3 outline the approach to emergent diagnoses in the critically ill trauma patient. The early assessment of a trauma patient’s circulatory status is crucial and includes hemorrhage control. An algorithmic approach is designed to localize the cause, as well as direct intervention. In penetrating trauma, the bleeding site(s) and therefore the differential diagnosis of circulatory problems is relatively limited as compared to the patient who has sustained significant blunt trauma. In victims of blunt trauma, the goal of management often focuses on localizing the injury: (1) to obvious external hemorrhage; (2) to long bone fractures; (3) to pelvic fractures; or (4) to internal hemorrhage.

The goal of the initial assessment in the ED is to determine whether the patient is in shock. If so, the decision making process turns to an assessment of volume status. If the patient is hypovolemic, immediate resuscitation is initiated. Hemorrhagic shock prompts the emergency clinician to locate the source immediately and target interventions, with ongoing reassessment.

Although mechanisms of injury alone cannot be relied on to predict all injuries caused by blunt major trauma,7 common patterns of injuries can be anticipated and specifically assessed in ED patients (see Table 33.1). Although these injuries may be present, there is frequently significant overlap between mechanism and injury. In this section, the differential diagnoses of various presentations are discussed.

Victims of trauma often present with altered mental status. Although acute neurologic injuries are the primary consideration, a variety of nontraumatic entities may also affect the patient’s presentation or be present in isolation. These include acute intoxication with drugs or alcohol, preexisting medical conditions (eg, hypoglycemia, hyponatremia) and behavioral and mental health conditions. A breath alcohol test or serum alcohol level is indicated for the trauma patient with altered mental status, although waiting for the results should not delay emergent head

Breathing assessment with critical diagnoses

Is breathing adequate?
- Assess oxygenation
- Assess ventilation

No

Is there respiratory distress?

No

- Consider empirical narcan
- Consider empirical glucose
- Identify and treat nontraumatic causes of hypoxia and hypoventilation

Yes

Are bilateral breath sounds present?

Yes

Identify and treat:
- Flail chest
- Cardiac injury
- Pulmonary contusion

No

Identify and treat:
- Tension pneumothorax
- Open pneumothorax
- Massive hemothorax

Proceed to circulation assessment

Fig. 33.2. Breathing assessment algorithm.
Circulation assessment with hemorrhage control

Is the patient in shock?

No

Continue to eFAST exam and secondary survey

Yes

What is the cause?

Nonhemorrhagic?
  • Tension pneumothorax
  • Cardiac tamponade
  • Cardiogenic
  • Neurogenic
  • Septic

Treat etiology

Hypovolemic?
  • Blood loss (principle cause in trauma)
  • Fluid loss

Locate hemorrhage
  • Physical exam
    • External
    • Thoracic
    • Abdomen
    • Pelvis
    • Long bone
  • Diagnostic adjuncts
    • Chest x-ray
    • Pelvis x-ray
    • eFAST
    • CT scan

Targeted interventions

Resuscitation
  • Adequate IV access
    • Minimum—two bore IVs
  • Balanced resuscitation
    • 1:2 L warmed isotonic fluids
    • Packed red blood cells, platelets, plasma
    • 2:1:1 vs 1:1:1 ratio
  • Prevent hypothermia
  • Consider tranexamic acid 1-g IV bolus followed by 1-g IV infusion over 8 hours

Locate hemorrhage
  • Direct pressure
  • Tourniquet

Pelvic fracture
  • Reduce pelvic volume
  • Wrap pelvis
  • Angio-emobolization

Internal hemorrhage
  Consider:
    • Laparotomy
    • Thoracotomy

Reassess response

CHAPTER 33  Multiple Trauma

![Flowchart of primary survey considerations](chart.png)

**Primary survey**

**Airway**
- Protecting airway?
  - Insufficient resp effort
  - GCS ≤ 8
  - Vomiting or bleeding

**Breathing**
- Adequate ventilation?
  - Equal breath sounds
  - Use of accessory muscles
  - Tachypnea
  - Oxygen saturations
  - Cyanosis

**Circulation**
- Signs of shock?
  - Tachycardia
  - Hypotension
  - Decreased capillary refill
  - Cool/mottled extremities

**Special considerations based on mechanism of injury**

- **Blunt trauma**
  - Severe maxillofacial injuries
  - Cervical spine immobilization
  - Consider awake intubation for cervical spine injuries

- **Penetrating trauma**
  - Vascular injury
  - Significant bleeding
  - Airway displacement or obstruction

- **Blunt trauma**
  - Chest contusions
  - Flail segment
  - Bowel sounds in chest

- **Penetrating trauma**
  - Chest injury
  - Significant bleeding
  - Sucking chest wound

- **Blunt trauma**
  - Maintain in-line immobilization
  - Assess for laryngeal/tracheal injury
  - Anticipate blood/ emesis in airway

- **Penetrating trauma**
  - Watch for expanding hematoma
  - Anticipate significant bleeding
  - Impaired video/ fiberoptic techniques

**Preparation for intubation**

**Blunt trauma**
- Maintain in-line immobilization
- Assess for laryngeal/tracheal injury
- Anticipate blood/ emesis in airway

**Penetrating trauma**
- Watch for expanding hematoma
- Anticipate significant bleeding
- Impaired video/ fiberoptic techniques

</table>
computed tomography (CT) when serious head trauma is suspected. Hypoglycemia causes depression of mental status and can be an inciting factor in major trauma. Point of care glucose testing is commonly performed by prehospital providers, but normal glucose levels should be confirmed after arrival in the ED. Minor mechanisms of injury with significant mental status changes may be a clue to a concomitant nontraumatic cause of altered mental status in these patients. Chronic medication use and comorbidities may contribute to the incidence of traumatic injuries and complicate the ED management of these patients. In addition to oral or injectable agents used to control diabetes, medications used for hypertension may result in bradycardia or transient hypotension, with decreased levels of consciousness as the cause of trauma. Use of diuretics or anticholinergic medications or psychiatric illness may lead to hyponatremia. Seizures have a postictal state and also may result in (usually minor) injury, but major trauma can result from seizures occurring while driving or those causing a fall from heights or submersion in water. Anticoagulants present a high risk state for any patient sustaining trauma, and patients on warfarin or newer anticoagulants or antiplatelet agents should undergo neuroimaging with even minor mechanisms of injury.

Hypotension is a significant finding in the acute trauma patient, and all such patients warrant a thorough evaluation for acute hemorrhagic shock. If hypotension persists and no clear source of hemorrhage is identified, other causes of hypotension must be considered. Neurogenic shock, associated with a spinal cord injury, is the next most likely cause when paralysis is identified. Acute myocardial infarction and cardiogenic shock due to severe myocardial contusion or underlying cardiac abnormalities, or hypotension caused by preexisting sepsis or blood loss (eg, gastrointestinal [GI] bleed), are considered if hypotension is present and no clear cause has been identified.

Finally, a critical tenet of trauma management is to avoid distraction by what might appear as an obvious injury. Traumatic amputations, gaping wounds, complex open fracture dislocations, and combative patient behavior frequently distract providers from their structured trauma evaluation. Approaching patients in a systematic way, using the primary and secondary surveys, will help prevent overlooking significant acute injuries. Similarly, complete exposure and a head to toe examination of the trauma patient will identify otherwise occult injuries, which may be concealed on the back or may be in the axilla or perineum.

**DIAGNOSTIC TESTING**

**Laboratory Evaluation**

Laboratory testing in the trauma patient should be guided by clinical assessment and the needs of the individual patient. Used wisely, these studies may provide an objective measure of the adequacy of resuscitation, guide transfusion decisions, assess for coagulopathy, provide baseline information for ongoing assessment, and detect and aid in the management of comorbid conditions, such as renal insufficiency and diabetes. Electrolyte levels, liver function studies, international normalized ratio (INR), urinalysis, blood typing and screening (or crossmatching, depending on severity of injury) and lactate levels or base deficit should be determined in all critically ill trauma patients. A pregnancy test should be performed in all female trauma patients of childbearing age. Serum β-human chorionic gonadotropin (β-hCG) testing can avoid the delays in obtaining a urine specimen.

Lactate level, base deficit, and anion gap determinations can help identify subclinical hypoperfusion and track the adequacy of resuscitation. Central venous oxygenation also has been used to assess adequacy of resuscitation. Research into earlier markers of hypoperfusion continues. We recommend determining the serum lactate level to evaluate for adequacy of resuscitation in trauma patients with abnormal vital signs suggestive of hypovolemia or altered mental status or other individuals for whom clinical assessment may be unreliable—older patients, those with comorbid conditions or medications that may affect vital signs (eg, beta blockers), or those with mechanisms with high risk for occult injury (see Table 33.1).

A type and screen are indicated for those patients with abnormal vital signs thought to be due to injury or mechanisms with risk for occult injury. A crossmatch should be ordered in those with persistently abnormal vital signs. If transfusion is needed prior to crossmatched blood being available, the provider can temporize with type-specific blood or type O-negative in women of childbearing age or type O-positive in other populations.

An INR should be ordered in all critically injured patients, those with ongoing hemorrhage requiring transfusion, and those on anticoagulants. The INR, however, does not provide a rapid comprehensive picture of the clotting process. In patients with extensive bleeding or undergoing massive transfusion, thromboelastography (TEG) or thromboelastometry (ROTEM) testing is used to aid the early diagnosis of trauma coagulopathies and direct blood and blood product transfusion. These evaluations are most beneficial for patients undergoing massive transfusion.

In the noncritical patient, determination of electrolyte levels can be reserved for those with underlying medical conditions for whom assessing or monitoring those values will be helpful. A complete blood count provides baseline information important for those at risk for ongoing bleeding or history of anemia. Liver function testing and serum lipase level determination should be carried out when blunt hepatic or pancreatic injury (eg, handlebar injury) is likely or comorbid conditions, including alcoholism, exist.

**Radiographic Evaluation**

Before the advent of CT scanning and advances in our understanding of the limitations of imaging, virtually all significantly injured patients underwent portable, plain radiographic imaging of their cervical spine, chest, and pelvis. This has now been largely supplanted by the selective use of portable plain radiography, bedside ultrasound (eFAST), and advanced imaging, usually CT scanning.

An eFAST examination should be performed on all patients with multisystem trauma or isolated trauma to the torso. Sonographic evidence of free intra-abdominal, intrathoracic, or pelvic hemorrhage, pneumothorax, and pericardial effusions or cardiac tamponade directs management of the patient. A positive abdominal scan for free fluid in hypotensive patients can identify those in need of emergent laparotomy, with good sensitivity. The sensitivity for injury may not be as high in the pediatric population, but in adult and pediatric populations, the absence of intraperitoneal blood on bedside US does not rule out intra-abdominal injury. US evaluation of the inferior vena cava is useful for assessing volume status, but is not part of the eFAST examination. Further discussion and suggested algorithms are found in Chapter 39.

Cervical spine imaging by plain radiographs in the trauma bay is of very limited value and has been largely supplanted by cervical spine imaging by CT. Patients with neurologic deficits are presumed to have spinal cord injury until proven otherwise, and a so-called normal cervical spine radiograph is not sufficient to rule out injury; spinal precautions should be continued. We recommend using the NEXUS (National Emergency X-Ray Utilization Study) criteria, which include absence of posterior midline tenderness, focal neurologic deficit, altered mental status, intoxication, or distracting injury. When a patient is not cleared by the NEXUS criteria, a CT scan of the cervical spine should be
obtained.\textsuperscript{52} If the neurologic examination is normal, a normal CT scan of the cervical spine is sufficient to exclude injury; further imaging is not necessary.\textsuperscript{53,56} Further diagnostic algorithms regarding spine imaging can be found in Chapter 36.

Imaging of the chest early in the evaluation of the multiple trauma patient can provide important information about potentially life-threatening injuries. US is superior to a supine portable chest x-ray as the initial screening tool for pneumothorax and hemothorax.\textsuperscript{42-45} We recommend that thoracic US be used in the initial screening of the blunt trauma patient with a significant mechanism of injury to identify life-threatening pneumothorax or hemothorax. If US is not available, portable chest x-ray should be used as the initial screening modality. A normal chest x-ray does not exclude intrathoracic injury; sensitivity for intrathoracic injury is low.\textsuperscript{40,41} Injuries not detected by chest x-ray, however, generally do not result in worse outcomes. Chest CT should be performed in those with significant chest pain, dyspnea, sternal tenderness, or abnormal thoracic US or chest x-ray findings. Chest CT is not required in asymptomatic blunt trauma victims with a normal chest x-ray.\textsuperscript{42-45}

There is evidence that thoracic imaging can be avoided altogether in blunt trauma patients with very low risk of thoracic injury. The criteria for obtaining imaging in one large validation study are age older than 60 years, rapid deceleration mechanism, chest pain, intoxication, abnormal alertness and mental status, distracting painful injury, and tenderness to chest wall palpation. This rule has a sensitivity of 99.8\% and negative predictive value of 98.5\%.\textsuperscript{46} However, these criteria have not been adopted on a wide scale. Adoption of these or modified criteria may occur by consensus among the key services involved (typically, emergency medicine, trauma surgery, radiology) at the local level as a way to decrease costs and radiation exposure.

In patients with a stab wound to the chest and an initial normal thoracic US or chest x-ray, routine use of chest CT is not indicated.\textsuperscript{47,48} Asymptomatic patients can undergo a repeat chest x-ray in as little as 1 hour, rather than the traditional 6 hours after an initial normal chest x-ray, to exclude significant pathology.\textsuperscript{49}

Pelvic fractures can cause significant hemorrhage, and early recognition of fracture and closure of the pelvic space can mitigate hypotension in these patients. In hemodynamically unstable patients, a portable pelvic x-ray should be obtained in the trauma bay. The sensitivity for an anteroposterior pelvic x-ray to identify all possible fractures is not high; however, an abnormal x-ray showing an open book fracture or vertical displacement of the posterior pelvis should alert the emergency clinician to the need for a pelvic binder and possible embolization or surgical fixation to control ongoing pelvic hemorrhage. Hemodynamically stable patients with pelvic tenderness or a distracting injury, or those with severe mechanisms of injury and altered mental status, should have their pelvis imaged. If the patient is undergoing CT of the abdomen and pelvis as part of the trauma assessment, we recommend using the bone windows of the CT scan rather than obtaining a pelvic x-ray.\textsuperscript{50,52} Hemodynamically stable patients who are awake, alert, and asymptomatic, with a normal pelvic physical examination, do not require pelvic x-rays.\textsuperscript{51,52} Similar studies have suggested the same for pediatric patients.\textsuperscript{53,54} Further discussion of pelvic trauma can be found in Chapter 48.

In blunt multiple trauma victims, imaging with an abdominal-pelvic CT scan (AP-CT) is recommended for those with abdominal pain or tenderness, significant mechanism of injury (see Table 33.1), abnormal eFAST examination, gross hematuria, or unreliable examination (eg, altered mental status, distracting injury, head injury). The presence of a seat belt sign is associated with an internal abdominal injury (IAI) and should prompt a CT scan.\textsuperscript{55} Blunt multiple trauma victims who have a Glasgow Coma Scale (GCS) score of 15, normal abdominal physical examination, negative eFAST, and normal laboratory results can forego a CT scan; however, they should have a period of observation, repeat eFAST examination, and repeat hemoglobin level determination.\textsuperscript{55,56}

Indications for imaging of the head, spine, and extremities are covered in the respective chapters. Patients with moderate or severe head injury should have their head imaging completed as soon as possible after the primary survey, eFAST examination, and brief secondary survey. Imaging of the thoracic and lumbar spines and extremities can be delayed until other life-threatening injuries have been investigated and managed.

**MANAGEMENT**

**Out-of-Hospital Management**

Management of the trauma patient frequently begins before arrival in the ED by first responders. The goals of out-of-hospital care include intervention in immediately life-threatening injuries, prevention of additional injury, and rapid transport to trauma centers for definitive care.

Most life-threatening injuries that require intervention by out-of-hospital providers are related to airway, breathing, and circulation (the ABCs). Endotracheal intubation may be required for patients with severe trauma, particularly head trauma with coma, and for those with significant trauma when transport times may be prolonged. Tension pneumothorax compromises ventilation and perfusion and requires needle or other thoracotomy when suspected. Systemic hypotension with impaired end-organ perfusion necessitates restoration of intravascular volume to a level sufficient to provide perfusion, but not and attempt to restore normal blood pressure.

Preventing additional injury requires an awareness of not only clinically evident abnormalities but also potentially more serious injuries. Coordinated extraction and transport with cervical immobilization, spinal precautions, intensive hemodynamic monitoring, and stabilization of fractures to prevent neurovascular compromise are examples of assuming the most serious injuries exist in multiple trauma patients.

**Emergency Department**

Because multiple trauma patients have a variety of injuries from varying mechanisms, the initial focus is directed at overall resuscitative care, with emphasis on performing interventions in the optimal sequence.

For level 1 trauma centers, the American College of Surgeons (ACS) requires the presence of a board-certified general surgeon to be present in the hospital 24 hours each day. The trauma surgeon is expected to be present in the hospital within 15 minutes after arrival of trauma patients to the ED (Box 33.1).\textsuperscript{57} As the specialty of emergency medicine has evolved, and the number of residency-trained and board-certified emergency clinicians has increased, the need for a surgeon for all trauma patients has been increasingly debated; outcomes are equivalent when the trauma team is led by a surgeon or an emergency clinician.\textsuperscript{58} Most trauma resuscitations in the community are performed by emergency clinicians, with consultation by a surgeon or surgical subspecialist based on identified injuries.

The priorities in the treatment of trauma patients are similar to those for any other life-threatening condition. Securing the airway, maintaining ventilation, controlling hemorrhage, and treating shock are the first priorities.

The goals of airway management are threefold—airway protection, adequate oxygenation, and adequate ventilation. The decision to intubate may go beyond these three tenets because the potential for deterioration in clinical status should be taken into account. Patients may have an obvious need for early intubation identified during the primary survey. Others will have serious
injuries detected later in their evaluation or will have deteriorated and require intubation. Still others will require intubation based on their overall clinical course and constellation of injuries, rather than for any one clear indication.

Airway protection is necessary for many trauma patients. Airway obstruction necessitates immediate intervention. Obstruction from debris, blood, or vomitus may be removed with suction. Neck or facial trauma may cause more complicated problems. Swelling, distorted anatomy, and hematoma formation may all contribute to impending obstruction. Early airway control is safest because these conditions may rapidly worsen. The inability to protect the airway adequately, such as in patients with depressed levels of consciousness, is another indication for intubation. Airway control is recommended for patients with depression of consciousness sufficient to compromise airway protection (usually cited as a GCS score <9).36 Alcohol intoxication can be an important confounder in the early neurologic assessment of these patients. In patients who do not immediately require airway protection, close observation over time for neurologic recovery to a normal state is necessary.

As a general rule, all trauma patients initially should be placed on supplemental oxygen. When oxygenation on room air is adequate, low-flow (3 L/min) nasal cannula oxygen is sufficient. When oxygenation is compromised, face mask oxygen at a high flow rate is required. Restoring adequate oxygenation has a direct effect on the outcome of many trauma patients, particularly head-injured patients. Maintenance of the arterial oxygen concentration \((P_{aO_2})\) above 60 mm Hg has been recommended by the Brain Trauma Foundation, a recommendation that has not changed since 2007. Certain ventilatory problems, such as pneumothorax or hemothorax, may require tube thoracostomy in addition to intubation. Placement of the chest tube before undertaking intubation, if possible, may improve the patient’s hemodynamic status and decrease the risk of serious deterioration related to the use of intubating medications and initiation of positive pressure ventilation.

If the patient’s condition allows, a detailed neurologic examination is important before administering neuromuscular blocking agents, which may confound later evaluation. Correlation of head CT scan findings with neurologic status is critical to making any decisions regarding operative intervention for intracranial hemorrhage. Also, documentation of neurologic function or deficit is essential in the setting of a potential spine injury. Most patients will not have been cleared of cervical spine injury before intubation, so in-line spine stabilization and the most gentle possible technique are important. We recommend videolaryngoscopy with rapid sequence intubation as the primary method to secure the airway in the severely traumatized patient16–22 (see Chapter 1). Videolaryngoscopy has been shown to reduce spine movement and generally achieves superior laryngeal views when compared with conventional direct laryngoscopy. When a potentially unstable spine injury has been identified, some emergency clinicians prefer to use a flexible bronchoscope for intubation. Overall, the choice of intubation technique will be based on the clinical scenario and emergency clinician’s determination of what is most likely to accomplish the desired task in his or her hands. Blind nasotracheal intubation is undesirable in the trauma patient. Nasotracheal intubation using a flexible bronchoscope may be valuable in patients with a suspected airway or unstable cervical spine injury, performed as part of a prepared awake intubation (see Chapter 1).

A surgical airway is indicated in cases of failure of or contra-indication to intubation. Cricothyrotomy is the preferred method, although it is performed in a small minority of all trauma cases requiring airway management, and the incidence has been decreasing because of the availability of better alternative rescue devices when intubation fails. When cricothyrotomy is required, we recommend the use of the four-step method or the no-drop cricothyrotomy technique, as described in Chapter 1. A variety of devices for percutaneous cricothyrotomy are also available, but only those using the Seldinger technique are sufficiently reliable and safe.

Control of external hemorrhage and rapidly establishing IV access are essential early steps in the management of the acute trauma patient. This has been discussed earlier (see “Primary Survey”).

The choice of fluids for resuscitation includes crystalloid, colloid, and blood products. Fluid replacement is generally based on a 3:1 ratio of fluids to blood loss. There are few clinically significant differences between lactated Ringer’s and normal saline solutions.30–32 The debate regarding the choice of colloids versus crystalloids for resuscitation is ongoing. No indisputable advantages of colloids have been demonstrated.34 Therefore, the less expensive and more readily available crystalloids are the mainstay of treatment. No clear benefit to the use of hypertonic saline has been established.35 Current Advanced Trauma Life Support (ATLS) guidelines standardize the ratio of replacement fluids to loss and recommend 2 L of crystalloid be infused in all patients in shock, followed by blood products. O-positive blood should be used, except in women of childbearing age. Type-specific blood should be used when available, but emergent transfusion should not be delayed. Massive transfusion protocols are commonly used for patients with severe hemorrhagic shock. Recent data have suggested that the use of a 1:1:1 ratio of plasma, platelets, and red blood cells may result in earlier hemostasis, although no significant difference in mortality was noted.36 We recommend the use of a 1:1:1 or 1:1:2 ratio of blood products based on specific institutional policies and procedures. Other transfusion ratios are less effective in resuscitation. The use of the antifibrinolytic agent tranexamic acid has been shown to decrease mortality in trauma patients at risk of major bleeding if given within the first hour following injury.4–10 Any trauma patient with clinically significant hemorrhage, or those who present in shock, should receive 1 g of tranexamic acid over 10 minutes, followed by a 1-g infusion over 8 hours. Mortality benefits of tranexamic acid have been shown when administered up to 3 hours after trauma, but earlier administration (within 1 hour) is superior.

In the severely injured, hypotensive trauma patient, restoration of normal blood pressure may be undesirable. The concept of permissive hypotension is based on the premise that resuscitation to a normal blood pressure may increase bleeding from an uncontrolled hemorrhage site or even from a site that is tenuously contained and not actively hemorrhaging. In permissive
Measure vital signs and level of consciousness

Step one
- Glasgow coma scale
- Systolic blood pressure (mm Hg)
- Respiratory rate

≤13
- ≤90 mm Hg
- <10 or >29 breaths/min
- (<20 in infant aged <1 year), or need for ventilatory support

No
- Assess anatomy of injury

Yes
- Transport to a trauma center.

Transport to a trauma center. Steps one and two attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the defined trauma system.

Step two
- All penetrating injuries to head, neck, torso and extremities proximal to elbow or knee
- Chest wall instability or deformity (eg, flail chest)
- Two or more proximal long bone fractures
- Crushed, degloved, mangled, or pulseless extremity
- Amputation proximal to wrist or ankle
- Pelvic fractures
- Open or depressed skull fracture
- Paralysis

Yes
- Yes

Yes
- Transport to a trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries. Consider consultation with medical control.

Step three
- Falls
  - Adults: >20 feet (one story is equal to 10 feet)
  - Children: >10 feet or two or three times the height of the child
- High-risk auto crash
  - Intrusion, including roof: >12 inches occupant site; >18 inches any site
  - Ejection (partial or complete) from automobile
  - Death in same passenger compartment
  - Vehicle telemetry data consistent with a high risk of injury
- Auto vs. pedestrian/bicyclist thrown, run over, or with significant (>20 mph) impact
- Motorcycle crash > 20 mph

Yes
- Transport to a trauma center, which, depending upon the defined trauma system, need not be the highest level trauma center.

Step four
- Older adults
  - Risk of injury/death increases after age 55 years
  - SBP < 110 might represent shock after age 65 years
  - Low-impact mechanisms (eg, ground level falls) might result in severe injury
- Children
  - Should be triaged preferentially to pediatric-capable trauma centers
  - Anticoagulants and bleeding disorders
    - Patients with head injury are at high risk for rapid deterioration
  - Burns
    - Without other trauma mechanism: triage to burn facility
    - With trauma mechanism: triage to trauma center
  - Pregnancy > 20 weeks
  - EMS provider judgment

Yes
- Transport to a trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries. Consider consultation with medical control.

No
- Assess special patient or system considerations

When in doubt, transport to a trauma center

Fig. 33.5. Triage decision scheme. EMS, Emergency medical services. (Adapted from American College of Surgeons, Committee on Trauma: Resources for the optimal care of the injured patient, Chicago, 2012, American College of Surgeons.)
hypotension, mean arterial pressure (MAP) is restored to a goal of approximately 50 mm Hg. Data have shown that this strategy leads to less blood product use, less bleeding, and lower incidence of coagulopathy.11,12 Permissive hypotension is contraindicated in the management of traumatic brain injury because of the risk of hypoperfusion.13-15 Rather than any particular MAP target, restoration of adequate tissue perfusion, with normal mentation or, more importantly, normalization of tissue oxygen saturation (StO₂) monitoring, is the clinically relevant endpoint in the resuscitation of the trauma patient.10-16

The role of ED thoracotomy (EDT) has become more selective to limit futile resuscitation efforts and minimize risk to providers. Patients with penetrating trauma who undergo cardiac arrest while in transport or in the ED are most likely to benefit from EDT. In contrast, cardiac arrest patients with blunt trauma, prolonged cardiopulmonary resuscitation (CPR), or delayed transport times generally have dismal outcomes that are not altered by EDT.17 Most institutions have protocols in place outlining criteria regarding when EDT should be performed. The National Association of EMS Physicians and ACS Committee on Trauma have published guidelines for withholding or terminating resuscitation efforts in out-of-hospital traumatic cardiac arrest patients. As a result, these guidelines often limit the transport of patients who would not likely benefit from EDT. Patients who may not be transported include any blunt trauma patient without vital signs at the scene, apneic or pulseless penetrating trauma victims without other signs of life, patients undergoing more than 15 minutes of CPR, and patients with transport times of more than 15 minutes after arrest.71-73 Suggested algorithms for the application of EDT are outlined in Figs. 33.5, 33.6, and 33.7. EDT is discussed further in Chapter 38. When EDT is performed, the goal is to manage rapidly correctable traumatic injuries and allow for transfer to the operating room for definitive intervention.

To assess disability, a rapid assessment of the patient’s neurologic status is necessary early in the ED course. If intubation is necessary early in the patient’s treatment, perform a brief neurologic examination, including level of consciousness, tone and motor ability for all four extremities (eg, spontaneous, purposeful, withdrawal to pain), anal sphincter tone (if obtunded or evidence of paralysis), and any lateralizing signs, prior to administration of the paralytic and induction agent.

**DISPOSITION**

The decision to admit the patient or transfer to a tertiary care facility should be coordinated based on available resources, consultation with the trauma surgeon, and consideration of institutional and regional guidelines. The ultimate disposition is dictated by a number of factors, including the patient’s condition, nature of the injury, and availability of surgeons, subspecialists, and anesthesiologists. Possible dispositions include transfer to the operating room, admission to the surgical service, limited observation in the ED, and transfer to another hospital. The level of care and monitoring established in the ED should be maintained throughout transfer. All equipment and medications needed for resuscitation and maintenance of vital functions should be available during the transfer, as should qualified personnel to oversee the patient’s care.

In cases of interhospital transfers, emergency clinicians at the two institutions should carefully coordinate all arrangements. Stabilizing measures are begun before the patient’s transfer, but decompensation in transit should be anticipated. Qualified personnel and necessary resuscitative equipment should accompany the patient. The compelling reason for transferring a patient with life-threatening trauma is the lack of resources or personnel to care for a patient’s particular injuries. Transfer should not be delayed for nonessential diagnostic procedures. All documentation and results of ancillary testing should accompany the patient in transfer.

In certain circumstances, the multiple trauma patient may not need admission or interhospital transfer. The decision to discharge these patients is evaluated carefully because many traumatic injuries may manifest in a delayed manner. When discharge is considered, thorough ED evaluation is necessary, with resources in place to ensure an optimal outcome—surgical consultation, where appropriate, attending radiologist support for image interpretation, and timely scheduled follow-up on an outpatient basis.

**KEY CONCEPTS**

- Immediately after a trauma patient arrives in the ED, the primary survey should be performed in a standardized fashion. The goal of the primary survey is to identify and initiate the treatment of critical, life-threatening injuries rapidly.
- The eFAST examination should take place early in the evaluation of the trauma patient, ideally as part of the primary survey. Thoracic examination of the trauma patient by ultrasound is more accurate than plain radiography.
- Any patient with potentially life-threatening injuries should have blood typing and screening performed. When transfusion is indicated, blood products should be transfused in a 1:1:1 or 1:1:2 ratio of plasma to platelets to packed red blood cells.
- Tranexamic acid is indicated for patients with evidence of significant hemorrhage or shock and is given as a 1-g bolus followed by a 1-g infusion over 8 hours. Results are best if started within 1 hour of injury but benefit may occur when it is given within 3 hours.

CHAPTER 33: QUESTIONS & ANSWERS

33.1. A 33-year-old mother and her 2-year-old-son are brought in by paramedics after they were both hit by a car moving at 15 mph. Although mother and child had an identical mechanism of injury, the son would be at greater risk for all the following injuries, with the following exception:

A. Head injury
B. Hypothermia
C. Intra-abdominal injury
D. Multisystem injury
E. Posttraumatic stress disorder

Answer: E. Injury patterns can differ significantly between adults and children subjected to similar mechanisms of trauma. The major anatomic distinctions relate to the smaller size and surface area, larger head-to-body ratio, and less protected abdominal cavity of the child. As a result, children are more vulnerable to multisystem injury in blunt trauma, including significant head and intra-abdominal injuries, as well as being at greater risk for hypothermia.

33.2. Which of the following is the goal of the primary survey?
A. Determine which consultations should be obtained.
B. Do an AMPLE (allergies, medications, past medical history, last meal, environments and events) history.
C. Obtain pertinent historical data from the paramedics.
D. Perform a radiographic evaluation.
E. Rapidly identify critical life-threatening diagnoses and begin treatment at the time of the diagnosis.

Answer: E. The emergency clinician should use a standardized approach to the initial evaluation of these patients. Following the Advanced Trauma Life Support (ATLS) algorithm in the primary survey allows the timely identification of critical diagnoses and intervention without delay. The primary survey should be performed in a standardized fashion immediately after the patient arrives in the emergency department. The goal of the primary survey is to identify critical, life-threatening diagnoses rapidly and begin treatment at the time of diagnosis. The goals of the secondary survey are to obtain pertinent historical data about the patient and injury as well as evaluate and treat injuries not found on the primary survey. An AMPLE history should be obtained.

33.3. An 89-year-old man who was a restrained front seat passenger with a history of hypertension, anxiety disorder, and dementia is being evaluated after a head-on collision. His home medications include an angiotensin-converting enzyme (ACE) inhibitor for the hypertension, lorazepam for the anxiety, and olanzapine (Zyprexa) for the dementia. The patient does not have any complaints but is noted to have a blood pressure of 80/50 mm Hg and heart rate of 100 beats/min. In evaluating the patient, you should suspect that the asymptomatic hypotension is most likely due to which of the following?
A. Antihypertensive medication use
B. Antipsychotic medication use
C. Benzodiazepine use
D. Blood loss

Answer: D. Lower extremity weakness, gait disturbances, decreased visual acuity, and the use of psychotropics, antihypertensives, and sedatives have been associated with falls in older adults, resulting in major injury. The use of these medications, particularly antihypertensives, should not be considered causative in trauma patients with hypotension until acute hemorrhage has been ruled out. In addition, anticoagulants, antiplatelet drugs, and aspirin are commonly prescribed, and their effects should be suspected and reversed, if warranted.

33.4. A critically injured, multisystem trauma patient has blood sent to the laboratory. The appropriate tests may determine the adequacy of resuscitation and need for blood transfusion. Hypoperfusion and inadequate resuscitation may be indicated by abnormalities in all except which of the following?
A. Anion gap
B. Base deficit
C. Central venous oxygen saturation
D. Lactate level
E. Magnesium

Answer: E. Laboratory markers can help identify patients who may not appear acutely ill but do have hypoperfusion, as well as track the adequacy of resuscitation. Lactate level, base deficit, and anion gap also predict outcome in the trauma patient. Following changes in the central venous oxygen saturation may also be worthwhile; low values in hemodynamically stabilized trauma patients have been shown to worsen outcome.

33.5. A severely injured, hypotensive trauma patient is being considered for permissive hypotension because she has a contained retroperitoneal hematoma and is not actively hemorrhaging. In permissive hypotension, the mean arterial pressure is restored to a goal of 50 mm Hg. Which of the following should help you decide against using permissive hypotension?
A. Age > 80 years
B. Age < 10 years
C. Associated traumatic brain injury
D. Hemoglobin of 10 g/dL
E. Intoxication

Answer: C. In the severely injured, hypotensive trauma patient, restoration of normal blood pressure may be undesirable. The concept of permissive hypotension is based on the concern that resuscitation to normal blood pressures may increase bleeding from a site that is contained and not actively hemorrhaging. In permissive hypotension, the mean arterial pressure (MAP) is restored to a goal of about 50 mm Hg. Studies have shown that this strategy leads to less blood product use, less bleeding, and lower incidence of coagulopathy. However, the provider should be aware that permissive hypotension is contraindicated in the management of traumatic brain injury because of the risk of hypoperfusion.
PRINCIPLES OF DISEASE

Background and Importance

Head trauma is a broad term describing an external trauma to the craniofacial area of the body from blunt, penetrating, blast, rotational, or acceleration-deceleration forces, the term head injury refers to a clinically evident injury on physical examination and is recognized by the presence of ecchymosis, lacerations, or deformities, and the term traumatic brain injury (TBI) indicates an injury to the brain itself.

Head trauma accounts for approximately 1.5 million emergency department (ED) visits annually in the United States; one-third of these are children younger than 14 years. Falls and motor vehicle collisions (MVCs) account for almost 75% of head trauma in the civilian population. TBI caused by blasts has resulted in disproportionate morbidity to combatants in the recent wars in Iraq and Afghanistan. As veterans return to the United States, the number of patients experiencing the consequences of TBI continues to increase.

Gunshot wounds (GSWs) to the head are particularly lethal; the overall mortality rate is estimated to be 90%, with 70% of deaths occurring at the scene. However, in a subset of these patients with good initial neurologic function, survival approaches 75%.

The ultimate survival and neurologic outcome of the brain-injured patient depends on the extent of TBI occurring at the time of injury (primary injury) and the effects of systemic insults (secondary injury), such as those caused by hypotension and hypoxia. Thus, clinical care of patients with TBI emphasizes early management to minimize the occurrence of secondary brain injury. Emergency clinicians influence the incidence and severity of primary brain injury only through injury prevention programs (see Chapter e2).

A number of terms describing mild traumatic brain injury (MTBI) have been used in the past, including minor, minimal, grade I, class I, and low risk. The American Congress of Rehabilitation Medicine defines a patient with MTBI as one who has a Glasgow Coma Scale (GCS) score of 13 to 15, with traumatically induced physiologic disruption of brain function, as manifested by at least one of the following: (1) any period of loss of consciousness less than 30 minutes; (2) any loss of memory for events immediately before or after the accident (posttraumatic amnesia should last <24 hours); (3) any alteration in mental state at the time of the accident (eg, feeling, dazed, disoriented, or confused); and (4) focal neurologic deficits that may or may not be transient (Box 34.1).

Individuals with MTBI are acutely at risk for serious intracranial injuries. Up to 17% of patients with suspected MTBI in the ED have abnormal computed tomography (CT) scans. Although the incidence of life-threatening lesions that require neurosurgical intervention in suspected MTBI is only about 1%, these patients have an important risk of subsequent deterioration from intracranial bleeding. If these cases are recognized and treated early, a full recovery is likely; if not, severe disability or death may ensue.

The GCS score was not originally intended for use in MTBI patients, and some authors have suggested that patients with a GCS score of 13 or 14 be excluded from the mild category and placed into the moderate-risk group due to the higher risk of neurosurgical intervention. However, a patient who is intoxicated from drugs and alcohol may present with a GCS score of 13 to 14. Furthermore, over 10% of patients who become comatose start with a GCS score of 15. Patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be a MTBI. Among MTBI patients, those with GCS scores trending downward (worsening neurologic status) are at higher risk of neurosurgical intervention and have a less favorable outcome than those with GCS scores trending upward (improving neurologic status).

Anatomy and Pathophysiology

Scalp and Cranium

The scalp consists of five tissue layers (Fig. 34.1). The skull is comprised of the frontal, ethmoid, sphenoid, and occipital bones and two parietal and two temporal bones. Each bone consists of solid inner and outer layers separated by a layer of cancellous bone tissue (the diploë). In adults, the bones of the skull average 2 to 6 mm in thickness; the bones in the temporal region are usually the thinnest of the skull. The cranial bones form a smooth outer surface of the skull, but within the cranial vault are many bone protrusions and ridges. Contrecoup injuries and contusions far from the site of head impact occur as the brain strikes against uneven bone surfaces. After the first few months of life, the cranial bones begin to fuse, ultimately forming the rigid, nonexpendable cranial vault. The inner aspect of the skull is lined with the periosteal dura, which is a thick connective tissue layer that adheres closely to the bone surface. The inner meningeal layer of the dura is the outermost covering of the brain. This dural membrane reflects back on itself to make folds within the cranial space. These folds serve to protect and compartmentalize different components of the brain. The midline falx cerebri separates the two cerebral hemispheres from each other. The tentorium cerebelli partitions the cerebellum and brainstem from the cerebral hemispheres. The U-shaped free margin of this dural fold is important in the pathology of the transtentorial herniation syndromes. Within the margins of the dural reflections, the two dural layers separate to form large dural venous sinuses. Injury to the dural sinuses is associated with significant morbidity and mortality because of the potential for uncontrolled hemorrhage.

Brain and Cerebrospinal Fluid

The brain is a semisolid structure that weighs approximately 1400 g (3 lb) and occupies approximately 80% of the cranial vault, with the remaining space occupied primarily by vasculature.
and cerebrospinal fluid. The brain is covered by three distinct membranes—the meningeal dura, arachnoid layer, and pia (Fig. 34.2). The location of traumatic hematomas relative to these membranes defines the pathologic condition and determines the consequences of the injury.

The brain is suspended in the cerebrospinal fluid (CSF), which provides some physical buffering for the brain during trauma. CSF is produced by the choroid plexus, located primarily in the lateral ventricles of the brain. CSF passes from the ventricular system into the subarachnoid space that surrounds the brain and spinal cord. The normal pressure exerted by the CSF is 65 to 195 mm H₂O or 5 to 15 mm Hg.

The blood-brain barrier (BBB) maintains the microenvironment of the brain tissue and CSF. Extracellular ion and neurotransmitter concentrations are regulated by movement across this barrier. When the BBB is intact, the ability of neuroactive drugs

**Fig. 34.1.** Layers of the soft tissues, skull, and meninges. The dermis is the outermost layer and is among the thickest layers of skin on the body. The underlying subcutaneous tissue contains the hair follicles and rich blood supply of the scalp. The galea, made of tough fascial tissue, contains the occipitofrontalis and temporoparietalis muscles, which move the scalp backward and forward, elevate the eyebrows, and wrinkle the forehead. Under the galea is a loose areolar tissue layer. The deepest layer of the scalp, the pericranium, is firmly adhered to the skull. (From Blumenfeld H: Neuroanatomy through clinical cases, Sunderland, 2002, Sinauer Associates, Incorporated.)

**Fig. 34.2.** Diffuse axonal injury (DAI), otherwise known as traumatic axonal injury (TAI), is characterized by axonal stretching leading to axolemmal disruption, ionic flux, neurofilament compaction, and microtubule disassembly, resulting in axonal swelling and disconnection. Axonal swelling and disconnection can lead to axon death. a, Normal neuron, b, c, Axon reaction to increasing stretch. d, Retraction balls have formed, and aggregates of axonal material lie along the course of the axon. (From Peerless SJ, Rewcastle NB: Shear injuries of the brain. CMAJ 96:577–582, 1967.)
to penetrate into the brain tissue usually depends on their lipid solubility. However, the biomechanics of a brain injury or post-traumatic cerebral edema can cause a disruption of the BBB for up to several hours after the insult. Prolonged disruption of the BBB further contributes to the development of posttraumatic vasogenic cerebral edema and higher maximum intracranial pressure.3

Cerebral Hemodynamics and Increased Intracranial Pressure

The brain has an extremely high metabolic rate, using approximately 20% of the entire oxygen consumed by the body and requiring approximately 15% of the total cardiac output. In the normal brain, cerebral blood flow (CBF) is maintained at constant levels. Optimal regional CBF is maintained by the ability of the cerebral vessels to alter their diameter in response to changing physiologic conditions. The responses of the cerebral vasculature to changing physiologic conditions protect the brain by increasing the delivery of oxygen to tissue, enhancing the removal of metabolic end products, and allowing nearly instantaneous adjustments to meet changing metabolic demands. Hypertension, alkalosis, and hypocarbia promote cerebral vasoconstriction, whereas hypotension, acidosis, and hypercarbia cause cerebral vasodilation.

Cerebral vasoactivity is also very sensitive to changes in the partial pressures of carbon dioxide and oxygen (Pco2 and Po2, respectively). The response to changes in Pco2 is nearly linear between Pco2 values of 20 and 60 mm Hg. In this range, lowering Pco2 by as little as 1 mm Hg decreases the diameter of cerebral vessels by 2% to 3%, corresponding to an overall change in CBF of 1.1 mL/100 g of tissue/min. This is the physiologic rationale for intentional hyperventilation in the setting of rapid and marked increases in intracranial pressure (ICP). Hyperventilation causes Pco2 to fall, resulting in cerebral vasoconstriction, but this is no longer recommended as a mechanism for reducing ICP. The cerebral vessels also respond to changes in Po2. As Po2 declines, cerebral vessels dilate to ensure adequate oxygen delivery to brain tissue. When brain injury occurs, increased CBF, vascular dilation, and a disrupted BBB promote vasogenic edema and can further increase ICP.4 Thus, avoiding or reversing hypoxia is essential in managing the brain-injured patient.

CBF also depends on the cerebral perfusion pressure (CPP), which is the pressure gradient across the brain. CBF remains fairly constant when CPP is 50 to 160 mm Hg. This is referred to as autoregulation and occurs with a mean arterial pressure (MAP) of 60 to 150 mm Hg. The determinants of CPP are MAP and the resistance to CBF produced by the mean systemic venous pressure and ICP. Because ICP is higher than mean systemic venous pressure, ICP effects predominate, and CPP can be approximated as follows:

\[
\text{CPP} = \text{MAP} - \text{ICP}
\]

If CPP falls below 40 mm Hg, autoregulation is lost and CBF declines, resulting in tissue ischemia and altered cerebral metabolism. Avoidance of hypotension or elevation in ICP in the head-injured patient helps ensure that CPP can be maintained.

The recommended target CPP value for improved outcomes is between 60 and 70 mm Hg. Whether 60 or 70 mm Hg is the minimum optimal CPP threshold is unclear and may depend on the patient’s autoregulatory status.10

Increased Intracranial Pressure

Increased ICP is defined as CSF pressure greater than 15 mm Hg (or 195 mm H2O) and is a frequent consequence of a severe TBI. Initially, as ICP increases as a result of a traumatic mass lesion or edema, CSF is displaced from the cranial vault to the spinal canal, offsetting the increased blood or brain volume. When this compensatory mechanism is overwhelmed, the elastic properties of the brain substance allow tissue compression to provide buffering for the increasing pressure. Depending on the location and rate of mass expansion and edema formation, the intracranial compensatory mechanisms can accommodate an increased volume of 50 to 100 mL. Beyond that, even small changes in intracranial relationships, such as from vasodilation, CSF obstruction, or areas of focal edema, may increase ICP. If ICP increases to the point at which CPP is compromised, vasoparalysis occurs and autoregulation is lost. The CBF then depends directly on the systemic MAP. With the loss of autoregulation, massive cerebral vasodilation occurs. Systemic pressure is transmitted to the capillaries, contributing to vasogenic edema, and further increase ICP.

ICP above 22 mm Hg is associated with increased mortality and warrants treatment.5 Methods to reduce elevated ICP include use of osmotic and diuretic agents and CSF drainage. Simple techniques to reduce ICP include head of bed elevation to 30 degrees and keeping the neck in a neutral position.1 Therapeutic hyperventilation, once almost universally used, is potentially harmful and is now used only in as a temporizing measure for a select group of patients for whom other measures are not available or have failed. If ICP is not controlled, herniation will occur, resulting in brainstem compression and cardiorespiratory arrest.

Cushing’s Reflex

Progressive hypertension associated with bradycardia and diminished respiratory effort is a specific response to acute, potentially lethal increases in ICP. This response is called Cushing’s reflex or Cushing’s phenomenon, and its occurrence indicates that the ICP has reached life-threatening levels. However, only one-third of cases of life-threatening increased ICP manifest the full triad of hypertension, bradycardia, and respiratory irregularity.

Definitions and Patterns of Injury

Traumatic Brain Injuries: Severe, Moderate, and Mild

Traditionally, TBI has been separated into the three broad categories of mild, moderate, and severe, primarily based on the GCS score following resuscitation and stabilization. Severe brain injury is defined as a TBI with a postresuscitation GCS score of 8 or lower, moderate as a GCS score of 9 to 12, and mild as a GCS score of 13 to 15. Overall, 80% of patients sustain MTBIs, 10% moderate brain injuries, and 10% severe brain injuries (Table 34.1).1 The term concussion is commonly used to describe MTBIs in sports.

The degree of brain injury following a MTBI or concussion also depends on the primary mechanism and magnitude of injury, secondary insults, and the patient’s genetic and molecular response.1-7 Primary damage is caused by the initial impact or force that although not usually as evident as severe TBI, may lead to smaller contusions, hematomas, axonal damage, and microvascular injury. Following a MTBI without evidence of lesions on computed tomography (CT) scans, there is a decrease in cerebral flow over the ensuing hours and days after injury,13 as well as cortical neurometabolic abnormalities.14,15 Traumatic axonal injury (TAI) is also an important determinant of outcome.16-18

Increasing evidence has suggested that a single MTBI can produce long-term gray and white matter atrophy, precipitate or accelerate age-related neurodegeneration, and increase the risk of developing Alzheimer’s, Parkinson’s, and motor neuron disease.19,20 In addition, repeated episodes of MTBI can provoke the development of chronic traumatic encephalopathy (CTE), a term used to describe clinical changes in cognition, mood, personality,
behavior, and/or movement occurring years following concus-
sion.\textsuperscript{11,22} CTE has recently been found to occur after other causes
of repeated head trauma, suggesting that any repeated blows to
the head, such as those that occur in American football, hockey,
soccer, and professional wrestling, in military personnel, and in
victims of physical abuse, can also lead to neurodegenerative
changes.\textsuperscript{20-23}

Direct and Indirect Injuries

Direct Injury. Direct head trauma occurs when the head is
struck, or its motion suddenly arrest by, an object. The resulting
damage to the skull and brain depends on the consistency, mass,
surface area, and velocity of the object striking the head. Direct
injury can also be caused by compression of the head. External
signs of trauma are frequently noted at the site of application of
the impact or compression force. The skull initially bends inward
at the point of contact. If the force is sufficient, a skull fracture
can occur. The cranium absorbs some of the applied energy,
whereas some energy is transmitted to the brain by shock waves
that travel distant to the site of impact or compression. With
sufficient and prolonged application of compression force, the
ability of the skull to absorb the force is overcome, and multiple
linear skull fractures occur. These resulting fractures can be
depressed if a high-energy rapid compression force is applied to
a small area of the skull. The extent of direct injury depends on
the vasoelastic properties of the underlying region of brain tissue,
duration of the force applied, magnitude of the force reaching the
brain tissue, and surface area of the brain that is affected.

Indirect Injury. In indirect brain injury, the cranial contents
are set into motion by forces other than the direct contact of
the skull with an object. A common example is an acceleration-
deceleration injury. No direct mechanical impact is sustained, but
the cranial contents are set into vigorous motion. As the bridging
subdural vessels are strained, subdural hematomas (SDHs) may
result.

Differential acceleration of the cranial contents occurs,
depending on the physical characteristics of the brain region. As
one brain region slides past another, shear and strain occur. These
movements result in diffuse injuries, such as a concussion or TAI.
Additional injury occurs as the movement of the intracranial
contents is abruptly arrested, and the brain strikes the skull or a
dural structure. Contrecoup contusions are an example of this
injury. In penetrating injury, the object produces pressure waves
that can strike structures distal to the path of the missile.

\textsuperscript{a}Persons who were hospitalized, died, or were transferred to another facility were excluded.
\textsuperscript{b}In-hospital deaths and patients who transferred from another hospital were excluded.
\textsuperscript{c}28 mortality records (from 2002-2006) were omitted because of missing age information.

Neurochemical Cascade

There can be secondary insults mediated through physiologic
events, which can decrease the supply of oxygen and energy to the
brain tissue, or a cascade of cytotoxic events, mediated by many
molecular and cellular processes. These events include activation
of inflammatory responses, imbalances of ion concentrations (eg,
potassium, calcium), an increase in the presence of excitatory
amino acids (eg, glutamate), dysregulation of neurotransmitter
synthesis and release, imbalance in mitochondrial functions and
energy metabolism, and production of free radicals.\textsuperscript{24}

Penetrating Head Trauma

The morbidity and mortality from missile injuries to the head
depend on the intracranial path, speed of entry, and size and type
of the penetrating object. Projectiles that cross the midline or
geographic center of the brain, pass through the ventricles, or
come to rest in the posterior fossa are associated with extremely
high mortality. High-velocity wounds are associated with greater
mortality than low-velocity injuries. Large missiles or missiles that
fragment within the cranial vault are usually fatal. The design of
the bullet and its fragmentation potential (capacity to deform or
fragment) also contribute to final tissue destruction and patients’
morbidity and mortality.

Tangential wounds are caused by an impact that occurs at an
oblique angle to the skull. If the missile has high velocity but low
energy, it can travel around the skull, under the scalp, without
passing through the skull. Intracranial damage, primarily cortical
contusions, can occur at the initial site of impact secondary to
pressure waves generated by the impact. Although many patients
with tangential GSWs have a GCS score of 15 on presentation, up
to 24% also have intracranial hemorrhage, and 16% sustain skull
fractures.\textsuperscript{25}

Most civilian penetrating brain injuries are penetrating missile
wounds, which are produced by moderate- to high-velocity pro-
jectiles discharged at close range. The penetrating object may
travel through the entire skull, bounce off the opposite inner table
of the skull and ricochet within the brain, or stop somewhere
within the cranial cavity.

As the bullet passes through the brain, a tissue cavity as much
as 10 times the diameter of the missile is created. A percussion
shock wave is also created, lasting 2 milliseconds but causing little
tissue destruction. The wounding capacity of a firearm is related
to the kinetic energy of its missile on impact and how much
energy is dissipated. Low-velocity missiles tend to be deflected by
in intracranial structures. The final track is therefore erratic and occasionally bears no relation to the exit or entrance site of the missile.

Scalp Wounds
The large blood vessels of the scalp do not fully constrict if they are lacerated and can be the source of substantial blood loss. Because the areolar attachments to the rest of the scalp are loose, scalp avulsions frequently occur through this layer. Subgaleal hematomas can become large because blood easily dissects through the loose areolar tissue. Hemostasis may be difficult to achieve, and blood loss may be significant to the point of causing hemodynamic compromise.

Skull Fractures
Skull fractures are local injuries caused by direct impact to the skull. Although the presence of a skull fracture does not always indicate underlying brain injury, the force required to fracture the skull is substantial, and all patients with skull fractures must be carefully evaluated to ensure that no additional injury is present. The pattern, extent, and type of skull fracture depend on the force of the impact applied and ratio of the impact force to the impact area. Clinically significant features of skull fractures include intracranial air, association with an overlying scalp laceration (open skull fracture), depression below the level of the skull’s inner table, and location over a major dural venous sinus or middle meningeal artery.

Linear Fractures
A linear skull fracture is a single fracture that goes through the entire thickness of the skull. Linear skull fractures are clinically important if they cross the middle meningeal groove or major venous dural sinuses; they can disrupt these vascular structures and cause the formation of epidural hematomas (EDHs). Most other linear skull fractures are not clinically significant.

Sutural diastasis is the traumatic disruption of a cranial suture. In adults, sutural diastasis often involves the coronal or lambdoid sutures. Sutural diastasis usually occurs when a linear fracture extends into the suture line, and it is rare after sutures have undergone bone fusion. Comminuted skull fractures, which are multiple linear fractures that radiate from the impact site, usually suggest a more severe blow to the head than that producing a single linear fracture. A linear vault fracture substantially increases the risk of intracranial injury.

Depressed Fractures
Depressed skull fractures are usually caused by direct-impact injury with small blunt objects, such as a hammer or baseball bat. Most depressed skull fractures occur over the parietal or temporal regions. These fractures are clinically important because they predispose to significant underlying brain injury and to complications of head trauma, such as infection and seizures.

Basilar Fractures
Basilar fractures are linear fractures at the base of the skull, usually occurring through the temporal bone. Patients with basilar fractures are at risk for extra-axial hematomas because of the proximity of the fracture to the middle cerebral artery. Dural tears, resulting from a basilar skull fracture, may produce a communication among the subarachnoid space, paranasal sinuses, and middle ear. This offers a route for the introduction of infection into the cranial cavity and is suggested by a CSF leak. These fractures are the result of considerable impact force and are highly associated with an underlying brain injury.

Extra-Axial and Intra-Axial Intracranial Injuries
Extra-axial refers to injury or bleeding that occurs within the skull but outside of the brain tissue. Intra-axial injury or bleeding occurs within the brain tissue itself. Extra-axial intracranial lesions include epidural hematoma, subdural hematoma, traumatic subarachnoid hemorrhage, and subdural hygroma. Intra-axial intracranial lesions include traumatic axonal injury, cerebral and cerebellar contusions, and cerebral and cerebellar hematomas.

Extra-Axial Injury
Epidural Hematoma. An EDH is bleeding that occurs between the inner table of the skull and dura. Most EDHs result from a direct-impact injury that causes a forceful deformity of the skull. Often, a fracture occurs across the middle meningeal artery, or vein, or a dural sinus. The temporoparietal region is the most likely site for an EDH. The high arterial pressure of the bleeding vessel dissects the dura away from the skull, permitting hematoma formation.

EDH is primarily a disease of the young and accounts for up to 5% of all patients who have experienced TBI. EDHs are rare in older adults and children younger than 2 years because of the close attachment of the dura to the skull in both patient populations.

Subdural Hematoma. A SDH is a hemorrhage that occurs between the dura and brain and is usually caused by acceleration-deceleration injuries. SDH occurs most commonly in patients with brain atrophy, such as alcoholic or older patients, because bridging vessels traverse greater distances than in patients with no atrophy. As a result, the vessels are more likely to rupture with rapid movement of the head. Once they are ruptured, blood can fill the potential space between the dura and arachnoid. SDH is much more common than EDH, occurring in up to 30% of patients with severe head trauma. The slow bleeding of venous structures delays the development of clinical signs and symptoms. As a result, the hematoma compresses the underlying brain tissue for prolonged periods and can cause significant tissue ischemia and damage. Approximately 20% of patients will present with a bilateral SDH. The prognosis of SDH does not entirely depend on the size of the hematoma but rather on the degree of brain injury caused by the pressure of the expanding hematoma on underlying tissue or by other intracranial injuries. Mortality is highest in older adults, patients who have a GCS score of 8 or less, and those with signs of acute herniation syndrome on initial ED presentation. Posterior fossa SDHs make up less than 1% of all reported SDHs. They are caused by occipital trauma that tears bridging vessels or venous sinuses and have a very poor prognosis.

Traumatic Subarachnoid Hemorrhage. A traumatic subarachnoid hemorrhage (SAH) is blood within the CSF and meningeal intima and probably results from tears of small subarachnoid vessels. Traumatic SAH is detected on the first CT scan in up to one-third of patients with severe TBI and ultimately is identified in almost 50% of patients with severe head trauma. It is therefore the most common CT scan abnormality seen after head trauma. Data from the National Traumatic Coma Data Bank have demonstrated a 60% unfavorable outcome in severely brain-injured patients when traumatic SAH is present compared with a 30% unfavorable outcome when it is not present. Traumatic SAH also is considered a risk factor for early mortality.
Subdural Hygroma. A subdural hygroma (SDHG) is a collection of clear, xanthochromic blood-tinged fluid in the dural space. The pathogenesis of an SDHG is not certain. It may result from a tear in the arachnoid that permits CSF to escape into the dural space or effusions from injured vessels through areas of abnormal permeability in the meninges or in the underlying parenchyma. They may accumulate immediately after trauma or in a delayed manner.

Intra-Axial Injury

Diffuse Axonal Injury and Traumatic Axonal Injury. Prolonged traumatic coma not caused by mass lesions or ischemic insult is thought to result from diffuse axonal injury (DAI). Although the term diffuse axonal injury has been widely adopted, the distribution of axonal injury is usually not diffuse but multifocal. Axonal injury occurs on a spectrum, with milder cases primarily localized. Furthermore, DAI has been used to describe axonal injury from nontraumatic causes in other neurologic conditions. Accordingly, the term traumatic axonal injury is preferred, particularly in milder cases. In more severe cases, when the axonal injury is more diffuse, the term diffuse traumatic axonal injury can be used.

In TAI, axons sustain a primary insult in which they are torn (axotomy) or stretched, and secondary insults lead to axonal swelling and disconnection and can lead to axon death (see Fig. 34.2). Moreover, acute uncoupling of cerebral blood flow, metabolism, and apoptosis are thought to be the important factors linked to axonal cell death after TAI.

Most patients with TAI present with persistent traumatic coma that begins immediately at the time of trauma; however, some patients may recover consciousness briefly before lapsing into prolonged coma. Because diagnostic studies cannot predict the extent of the axonal damage, the severity of the injury is determined by the clinical course. Clinical grades of diffuse TAI have been based on length of coma: (1) grade I (mild)—coma for 6 to 24 hours; (2) grade II (moderate)—coma for longer than 24 hours but not decerebrate; (3) grade III (severe)—coma for longer than 24 hours and decerebrate or flaccid. Currently, no early clinical or biomarker predictor exists that differentiates patients with mild, moderate, or severe diffuse TAI. Experimental laboratory data have indicated that neurons can partially repair and regenerate damaged axons.

Cerebral Contusions. Contusions are bruises on the surface of the brain, usually caused by impact injury. Most often, contusions occur at the poles and inferior surfaces of the frontal and temporal lobes, where the brain comes into contact with bone protuberances in the base of the skull. If the contusion occurs on the same side as the impact injury, it is a coup injury; if it occurs on the opposite side, the contusion is a contrecoup injury. Contusions also often develop in the brain tissue that underlies a depressed skull fracture. Multiple areas of contused tissue may be produced with a single impact, often in association with other intracranial injuries. Contusions are produced when parenchymal blood vessels are damaged, resulting in scattered areas of petechial hemorrhage and subsequent edema. Contusions develop in the gray matter on the surface of the brain and taper into the white matter. Often, subarachnoid blood is found overlying the involved gyrus. With time, the associated hemorrhages and edema of a contusion can become widespread and serve as a nidus for hemorrhage or swelling, thus producing a local mass effect. Compression of the underlying tissue can cause local areas of ischemia, and tissue infarction is possible if the compression is significant and unrelied. Eventually, these ischemic areas become necrotic, and cystic cavities form within them.

Intracerebral Hematoma. Intracerebral hematomas (ICHs) are formed deep within the brain tissue and are usually caused by shearing or tensile forces that mechanically stretch and tear deep small-caliber arterioles as the brain is propelled against irregular surfaces in the cranial vault. Resulting small petechial hemorrhages coalesce to form ICHs, with 85% in the frontal and temporal lobes. An ICH is often found in the presence of extra-axial hematomas and, in many patients multiple ICHs are present. Isolated ICHs may be detected in as many as 12% of all patients with severe head trauma.

Intracerebellar Hematoma. Primary traumatic intracerebellar hematomas are rare but can occur after a direct blow to the occipital area. Often, these patients have an associated skull fracture, posterior fossa EDH or SDH, or supratentorial contrecoup hematomas and contusions.

Primary and Secondary Brain Injuries

The acute clinical picture of the patient with TBI is dynamic and represents the sum of primary and secondary injury.

Primary Brain Injury

A primary brain injury is mechanical damage that occurs at the time of head trauma and includes brain lacerations, hemorrhages, contusions, and tissue avulsions. On the microscopic level, primary injury causes permanent mechanical cellular disruption and microvascular injury. Other than the evacuation of traumatic hematomas, no specific intervention exists to repair or reverse primary brain injury.

Following the primary injury, there is a cascade of events at the cellular and molecular level that continues for hours to days that contribute further to the brain injury. This secondary brain injury results from intracellular and extracellular derangements that lead to alterations in cell function and propagation of injury through processes such as depolarization, excitotoxicity, disruption of calcium homeostasis, free radical generation, BBB disruption, ischemic injury, edema formation, and intracranial hypertension.

Animal and human studies have revealed a complicated series of neurochemical, neuroanatomic, and neurophysiologic reactions after brain injury (Fig. 34.3). The cell has some compensatory mechanisms to protect itself from widespread damage, such as endogenous free radical scavengers and antioxidants. However, these systems are quickly overwhelmed, and the functional and structural integrity of the cell is threatened. Investigational agents aimed at specific steps in the destructive processes have suggested that some aspects of secondary brain injury may be reversed or modified. Multiple ongoing brain injury trials have been performed with numerous investigational therapeutic interventions; to date, none have proved useful in the clinical setting.

Secondary Systemic Insults

The final neurologic outcome after head trauma is influenced by the extent and degree of secondary brain injury. In turn, the amount of secondary brain injury depends on certain premorbid and comorbid conditions, such as the age of the patient and trauma-related systemic events. A primary goal in the emergency care of a head trauma patient is prevention or reduction of systemic conditions that are known to worsen outcome after TBI, such as hypotension, hypoxia, anemia, and hyperpyrexia.

Hypotension. Defined as SBP less than 90 mm Hg, this has been found to have negative impact on severe brain injury outcome. Systemic hypotension reduces cerebral perfusion, thereby potentiating ischemia and infarction. Hypotension is
associated with a near-doubling of the mortality from TBI and worse outcomes for patients who survive.35

Hypoxia. Defined as a Po2, less than 60 mm Hg, this occurs often in the brain-injured patient. Causes include the following: (1) transient or prolonged apnea caused by brainstem compression or injury after the traumatic event; (2) partial airway obstruction caused by blood, vomitus, or other debris in the airway of the traumatized patient; (3) injury to the chest wall that interferes with normal respiratory excursion; (4) pulmonary injury that reduces effective oxygenation; and (5) ineffective airway management, such as the inability to bag-valve-mask or intubate the patient in an effective or timely manner. When hypoxia is documented, the overall mortality from severe TBI may double.36 Hyperoxia also is associated with worse outcome after traumatic brain injury.37,38

Hypocarbia and Hypercarbia. Hypocarbia (Paco2 ≤ 35 mm Hg) and hypercarbia (Paco2 ≥ 46 mm Hg) are each associated with increased mortality following TBI. Hypocarbia causes cerebral vasodilation, with a resultant increase in cerebral edema and ICP, and thus is associated with a worsened neurologic outcome.39,40 Hyperventilation to induce hypocarbia has been discredited for patients with elevated ICP; current patient management emphasizes maintenance of normal to slightly reduced Paco2 levels.

Anemia. Anemia caused by blood loss can be detrimental to the head-injured patient by reducing the oxygen-carrying capacity of the blood, thus reducing the amount of necessary substrate delivered to the injured brain tissue. When anemia (hematocrit, 30%) occurs in patients with severe brain injury, the mortality rate increases.40 Other potential reversible causes of systemic insult in brain injury include hypercarbia, coagulopathy, and seizures.41

Hyperpyrexia. Hyperpyrexia (core body temperature > 38.5°C [101.3°F]) is also correlated with worse outcomes after TBI, its magnitude and its duration seem to contribute. The exact mechanism whereby it causes damage likely involves increased metabolism in injured brain areas, thus recruiting blood flow, with a resultant increase in ICP.41

Altered Levels of Consciousness

Consciousness is the state of awareness of the self and environment, and it requires intact functioning of the cerebral cortices and reticular activating system (RAS) of the brainstem. A patient who has sustained TBI typically has an altered level of consciousness (LOC), but reversible conditions that can alter mental status, such as hypoxia, hypotension, or hypoglycemia, should be corrected as they are identified. Head trauma patients may be hypoxic from injury to respiratory centers or from concomitant pulmonary injury. Hypotension from other associated injuries can compromise CBF and affect consciousness. Global suppression may result from an intoxicant consumed before the injury, hypoglycemia, posttraumatic seizure (PTS), or postictal period after a seizure from any cause. With increasing ICP from brain swelling or an expanding mass lesion, brainstem compression and subsequent RAS compression can occur.

Cerebral Herniation Syndromes

Cerebral herniation occurs when increasing cranial volume and ICP overwhelm the natural compensatory capacities of the central nervous system (CNS; Fig. 34.4). When the signs of herniation syndrome are present, however, mortality approaches 100% without rapid implementation of temporizing emergency measures and definitive neurosurgical therapy.

Uncal Herniation

The most common clinically significant traumatic herniation syndrome is uncal herniation, a form of transtentorial herniation. Uncal herniation is often associated with traumatic extra-axial hematomas in the lateral middle fossa or the temporal lobe. As compression of the uncus begins, the third cranial nerve (CN) is compressed; anisocoria, ptosis, impaired extraocular movements, and a sluggish pupillary light reflex develop on the side ipsilateral to the expanding mass lesion. As the herniation progresses, compression of the ipsilateral oculomotor nerve eventually causes ipsilateral pupillary dilation and nonreactivity.

Initially in the uncal herniation process, motor examination findings can be normal, but contralateral Babinski responses develop early. Contralateral hemiparesis develops as the ipsilateral peduncle is compressed against the tentorium. With continued progression of the herniation, bilateral decerebrate posturing eventually occurs; decorticate posturing is not always seen with the uncal herniation syndrome. In a certain percentage of TBI patients, the contralateral cerebral peduncle is forced against the opposite edge of the tentorial hiatus. Hemiparesis is then detected ipsilateral to the dilated pupil and mass lesion. This is termed Kernohan’s notch syndrome and causes false-localizing motor findings. As uncal herniation progresses, direct brainstem compression causes additional alterations in the LOC, respiratory pattern, and cardiovascular system. Mental status changes may initially be subtle, such as agitation, restlessness, or confusion, but soon lethargy occurs, with progression to frank coma. The patient’s respiratory pattern may initially be normal, followed by sustained hyperventilation. With continued brainstem compression, an ataxic respiratory pattern develops. The patient’s hemodynamic status may change, with rapid fluctuations in blood pressure and cardiac conduction. Herniation that is uncontrolled progresses rapidly to brainstem failure, cardiovascular collapse, and death.
Central Transtentorial Herniation

Less common than uncal transtentorial herniation, the central transtentorial herniation is demonstrated by rostrocaudal neurologic deterioration caused by an expanding lesion at the vertex or frontal or occipital pole of the brain. Clinical deterioration occurs as bilateral central pressure is exerted on the brain from above. The initial clinical manifestation may be a subtle change in mental status or decreased LOC, bilateral motor weakness, and pinpoint pupils (2 mm). Light reflexes are still present but are often difficult to detect. Muscle tone is increased bilaterally, and bilateral Babinski’s signs may be present. As central herniation progresses, both pupils become midpoint and lose light responsiveness. Respiratory patterns are affected, and sustained hyperventilation may occur. Motor tone increases. Decorticate posturing is elicited by noxious stimuli. This progresses to bilateral decorticate and then spontaneous decerebrate posturing. Respiratory patterns initially include yawns and sighs and progress to sustained tachypnea, followed by shallow slow and irregular breaths immediately before respiratory arrest.

Cerebellotonsillar Herniation

Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate downward through the foramen magnum. This is usually the result of a cerebellar mass or large central vertex mass causing the rapid displacement of the entire brainstem. Clinically, patients demonstrate sudden respiratory and cardiovascular collapse as the medulla is compressed. Pinpoint pupils are noted. Flaccid quadriplegia is the most common motor presentation because of bilateral compression of the corticospinal tracts. Although mortality is high, timely neurointensive care and neurosurgical intervention results in recovery to a minimal or moderate level of disability in over 50% of patients.

Upward Transtentorial Herniation

Upward transtentorial herniation occasionally occurs as a result of an expanding posterior fossa lesion. The LOC declines rapidly. These patients may have pinpoint pupils from compression of the pons. Downward conjugate gaze is accompanied by the absence of vertical eye movements.

**MODERATE AND SEVERE TRAUMATIC BRAIN INJURY**

**Clinical Features and History**

Although the history may be delayed by the need for emergent resuscitation and stabilization, details regarding the mechanism of injury, circumstances surrounding the injury, and any concomitant drug or alcohol use should be solicited. The patient, prehospital providers, or any witnesses should be queried as to loss of consciousness or seizure activity. The patient should be asked about recall of the incident and the time periods before and after and about any symptoms, including severe headache, nausea, vomiting, or amnesia. The past medical history should be obtained, with particular attention to coagulopathies such as hemophilia. In
addition, the patient’s medications, particularly antiplatelet agents, should be determined. If there has been a change in the patient’s GCS score, this should be noted.

The patient’s current LOC, as well as that immediately before and after the injury and at the arrival of first responders, should be determined. Worsening mental status or deteriorating GCS scores since the injury indicate the presence of moderate to severe injury. Witnessed seizures or apnea should be reported. If the patient is now awake but was unconscious at some point, it should be determined if the patient has returned to baseline mental status.

**Common Presentations of Specific Lesions**

**Epidural Hematoma**

The classic presentation of an EDH is described as head trauma producing a decreased LOC followed by a so-called lucid interval. Although the patient’s consciousness is less decreased during the lucid interval, a completely normal mental status may not return before a second episode of decreased consciousness occurs. The lucid interval is not pathognomonic for an EDH and occurs in patients who sustain other expanding mass lesions. Approximately 47% of patients with EDHs present classically. The development of symptoms and signs of EDH is entirely dependent on how quickly the EDH is developing within the cranial vault. Patients with an EDH often complain of a severe headache, sleepiness, dizziness, nausea, and vomiting. A small EDH may remain asymptomatic, but this is rare.

If the EDH is rapidly detected and evacuated, the functional outcome is excellent. Because of their rapid formation, EDHs from arterial bleeding are usually detected within hours after injury and often earlier in children. EDHs that develop from a dural sinus tear develop more slowly, and clinical manifestations may be delayed, with resultant delays in detection.

A posterior fossa EDH is the result of direct occipital trauma resulting in a skull fracture that disrupts a venous sinus is the usual cause, and most patients have external evidence of occipital injury. Most patients become symptomatic within 24 hours after injury, with complaints of headache, nausea, vomiting, and nuchal rigidity. Most patients eventually have a decreased LOC.

**Subdural Hematoma**

The patient’s clinical presentation depends on the amount of brain injury sustained at the time of trauma and the rate of SDH expansion. If the patient with an SDH was rendered unconscious at the time of trauma, the prognosis is poor; these patients often have concurrent TAI. The signs and symptoms after injury that produces an SDH are initially related to the other intracranial injuries that may have been sustained and then to the slow expansion of the SDH. SDHs are classified by the time to clinical presentation. Acute SDHs are symptomatic within 24 hours after trauma. Patients with acute SDHs often have a decreased LOC. Most patients with an SDH have a GCS score less than 8. Approximately 12% to 38% of patients will have a lucid period at some point in their presentation. The overall mortality of patients who have an SDH and require surgical intervention is 40% to 60%.

A chronic SDH becomes symptomatic 2 weeks or more after trauma. The signs and symptoms may be very subtle or nonspecific, but many patients demonstrate unilateral weakness or hemiparesis. Patients with unilateral chronic SDH have more frequent occurrence of hemiparesis than those with bilateral chronic SDH. Most report an altered LOC, but some patients are unable to recall the trauma or describe only a minor injury. A chronic SDH may have initially been a small asymptomatic SDH that eventually expanded owing to a combination of recurrent hemorrhage and escape of plasma into the hematoma. At some point, a critical mass is reached, and the chronic SDH becomes symptomatic.

Clinical manifestations of posterior SDH vary but usually include nausea, vomiting, headache, and decreased LOC. Occasionally, CN palsies may be found, as well as nuchal rigidity, cerebellar signs and symptoms, and papilledema.

**Traumatic Subarachnoid Hemorrhage**

An increased incidence of skull fractures and contusions is found in patients with a traumatic SAH (tSAH) compared with patients with no tSAH. The amount of blood within the tSAH correlates directly with the outcome and inversely with the presenting GCS score. Patients may complain of headache and photophobia.

**Subdural Hygroma**

Clinically, an SDH cannot be distinguished from other mass lesions. Often, patients have a decreased LOC or focal motor deficits. They may complain of headaches, nausea, and vomiting. The ICP can increase because of the mass effect, and signs of increased ICP may be present.

**Traumatic Axonal Injury**

The duration of loss of consciousness or coma following injury is directly related to the extent of axonal pathology in the brainstem. Even with extensive axonal pathology in the white matter, there may be little or no loss of consciousness if the brainstem is relatively spared. Therefore, it appears that the distribution, rather than the overall extent, of axonal pathology is important in determining consciousness immediately following TBI.

**Cerebral Contusion**

The clinical presentation of patients with contusions is frequently delayed. They may have sustained only a brief loss of consciousness, but the duration of posttraumatic confusion and obtundation may be prolonged. If contusions occur near the sensorimotor cortex, focal neurologic deficits may be present. Many patients with significant contusions make uneventful recoveries, but contusions may cause significant neurologic problems, including increased ICP, PTSS, and focal deficits.

**Intracerebral Hematoma**

The clinical effects of intracerebral hematomas depend on size and location and whether the bleeding is continuing. ICHs have been reported with all degrees of severity of head trauma. More than 50% of patients with ICH sustain loss of consciousness at the time of impact. The patient’s subsequent LOC depends on the severity of the impact and coexisting lesions. Combined with contusions, other concurrent lesions, and subsequent perilesion edema, an ICH can produce substantial mass effects and precipitate a herniation syndrome (Fig. 34.5).

**Traumatic Intracerebellar Hematoma**

The clinical presentation of an isolated traumatic cerebellar hematoma is similar to that of other posterior lesions. When other traumatic lesions are present, the picture may be confusing.

**Physical Examination**

In the setting of head trauma and suspected brain injury, management should be guided by the principles of trauma resuscitation.
A primary survey focusing on airway, breathing, and hemorrhage control should be performed expeditiously. After immediate life threats are adequately addressed, a secondary survey should evaluate for underlying head injury, brain injury, and neurologic compromise.

The head and neck should be carefully examined for external signs of trauma that may have also produced an underlying TBI. A scalp laceration, contusion, abrasion, or avulsion may overlay a depressed skull fracture. The clinical examination for a depressed skull fracture may be misleading. The mobility of the scalp can result in nonalignment of the fracture with an overlying scalp laceration. As a result, the skull underlying the laceration may be normal, with the depressed area several centimeters away. Scalp swelling may interfere with physical examination findings and hide any palpable bone defects. The signs and symptoms of a depressed skull fracture depend on the depth of depression of the free bone piece. About 25% of patients sustaining a depressed skull fracture report loss of consciousness. Neurologic deficits may be present, depending on the extent of underlying brain tissue injury.

Basilar skull fractures are often diagnosed by the clinical examination (Box 34.2), and the physical examination should evaluate for such signs as hemotympanum, periauricular or periorbital ecchymoses, and clear otorrhea or rhinorrhea. In the case of an impalement injury, the penetrating object should be left in place to be removed at surgery. Patients with basilar fractures are at risk for extra-axial hematomas because of the proximity of the fracture to the middle cerebral artery. Basilar fractures can compress and entrap the CNs that pass through the basal foramina, dislocate the bones of the auricular chain, and disrupt the otic canal or cavernous sinuses with subsequent injury to CNs III, IV, and V. Fractures of the sphenoid bone can disrupt the intracavernous internal carotid artery, creating the potential for the formation of pseudoaneurysms or carotid venous fistulae. The diagnosis of a basilar skull fracture is based on associated clinical signs and symptoms (see Box 34.2).

The percentage of concurrent cervical spine injury in patients with severe head trauma ranges up to nearly 20%. Often, other spinal regions are also injured. The neck should be evaluated for evidence of a cervical spine fracture. Carotid artery dissections caused by a hyperflexion-extension neck injury can occasionally be detected by auscultation of a carotid bruit. In these patients, a careful neurologic examination should assess for subtle asymmetry between the carotid arteries. Finally, all patients should undergo a thorough secondary evaluation after initial stabilization, evaluating for additional injuries, including an evaluation for spinal cord pathology.

**Acute Neurologic Examination**

**General.** The goals of the acute neurologic assessment of head trauma patients include detection of life-threatening injuries and identification of neurologic changes in the immediate post-trauma period. An accurate neurologic assessment in this period serves as a basis for comparison in subsequent examinations. An efficient neurologic examination in the emergency setting includes evaluation of mental status, GCS score, pupillary size and responsiveness, and motor strength and symmetry. If a formal GCS measure is not possible or is difficult because of comorbid confounders, the patient’s mental status should be described in as much detail as possible. Declining mental status after head trauma suggests increasing ICP from an expanding mass lesion or worsening cerebral edema, which may rapidly become life-threatening. The strongest predictors of outcome following moderate and severe TBI are age, pupillary reactivity, and GCS motor score. Additional predictors include CT characteristics, hypotension, hypoxia, laboratory parameters (eg, glucose, hemoglobin levels), and extracranial injuries.

**Clinical Characteristics of Basilar Skull Fractures**

- Blood in ear canal
- Hemotympanum
- Rhinorrhea
- Otorrhea
- Battle’s sign (retroauricular hematoma)
- Raccoon sign (peri orbital ecchymosis)
- Cranial nerve deficits
- Facial paralysis
- Decreased auditory acuity
- Dizziness
- Tinnitus
- Nystagmus

**Fig. 34.5.** Non–contrast-enhanced computed tomography (CT) scan of intracerebral hematoma and contusion in the left occipital region. The scan also shows layering of a tentorial subdural hematoma. Mass effect and early uncal herniation are visible as well.

**Glasgow Coma Scale.** The GCS is a 15-point scale used in an attempt to quantify the patient’s LOC and is an objective method of following the patient’s neurologic status (Table 34.2). It was originally developed during a time when CT scanning was not available to communicate changes in neurologic status in comatose patients with TBI (Fig. 34.6). The score assigns points based on the patients best eye opening (spontaneous opening = 4 to no response = 1), motor response (obeys commands = 6 to no response = 1), and verbal response (oriented = 5 to no response = 1). Due to its ease of use, it has been adopted in the routine
assessment of all trauma patients, including those with MTBI who are not comatose. However, the GCS score can reflect impairment from conditions other than brain injury, such as distracting injuries, intoxication from drugs and alcohol, hypoxemia, and sedative medications. Furthermore, patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be a mild brain injury. Although TBI is often categorized into mild, moderate, and severe based on the GCS score, it really represents a spectrum of injury.

Pupillary Examination. An evaluation of the patient's pupil size and responsiveness is performed early in the initial assessment of the head-injured patient. Pupillary asymmetry, the loss of the light reflex, or a dilated pupil suggests herniation syndrome as increasing pressure on the CN III results in compromise of the parasympathetic fibers and pupillary dilation on the affected side. However, use of the pupillary examination for localization of parasympathetic fibers and pupillary dilation on the affected side. Increasing pressure on the CN III results in compromise of the light reflex, or a dilated pupil suggests herniation syndrome. The rate of decerebrate posturing increases significantly in the presence of midbrain lesions.

Brainstem Function. In the acute setting, brainstem activity is assessed by the patient's respiratory pattern, pupillary size, and eye movements. The oculocephalic response (doll's eyes maneuver) tests the integrity of the pontine gaze centers. This response should not be elicited until cervical spine fractures have been ruled out. The oculovestibular response (cold water calorics) also permits assessment of the brainstem. Comatose patients no longer demonstrate nystagmus when cold water is placed in the ear canal; the only response is tonic deviation of the eyes toward the instilled cold water. This response is dampened by cerumen or blood in the patient's ear canal, and the tympanic membrane needs to be intact for this test to be performed.

In the severely head-injured patient, the CN examination is often limited to the pupillary responses (CN III), gag reflex (CNs IX and X), and corneal reflex (CNs V and VII). Facial symmetry (CN VII) can sometimes be assessed if the patient grimmaces with noxious stimuli. In patients who are awake and cooperative, a formal CN examination should be performed.

Differential Diagnosis

In the context of trauma, conditions presenting with an altered LOC include seizures and associated postictal state, intoxication with alcohol or drugs, and systemic trauma resulting in hypoxemia or hypoperfusion. A patient's mental status may also be impaired by sedatives or motor function may be altered by neuromuscular blocking agents administered prior to ED arrival. However, intraxial and extra-axial lesions may cause alterations in mental state and may coexist with other traumatic injuries. Head trauma may result in confounding injuries to other parts of the head or neck, including skull or facial bone fractures, cervical spine or spinal cord injuries, eye injuries, otolaryngeal injuries, and damage to blood vessels within the neck. Although a GCS score of 15 does not exclude the possibility of brain injury, a decreasing GCS score suggests an expanding intracranial lesion, which may be intracerebral or subdural or epidural. Signs include worsening headache, focal neurologic signs, confusion, and lethargy, which may progress to coma. Presentation of a subdural hemorrhage may be acute, subacute, or chronic. Epidural or intracerebral hemorrhages have an acute abrupt presentation, which may be delayed by minutes to hours from the initial injury. Patients with an epidural hemorrhage may have a lucid interval following a brief loss of consciousness or period of confusion. A skull fracture may be accompanied by underlying traumatic pathology, including brain contusions, dural tears, and vascular trauma. Given the proximity of the middle meningeal artery to the temporal bones, consider extra-axial hematomas (especially EDH) if there are signs of a basilar skull fracture. Decorticate posturing implies injury above
the midbrain, whereas decerebrate posturing is suggestive of a midbrain lesion. Pupil inequality and unilateral motor deficits may help localize a lesion. In vulnerable populations, consider nonaccidental trauma in all patients with brain injury. Furthermore, consider traumatic brain injury in all patients with head trauma and advanced age or those on anticoagulant or antiplatelet agents, regardless of symptoms. With age, the brain atrophies and creates more space within the cranial vault for blood to accumulate, so older adults can have significant hemorrhage and not show signs of deterioration.
**Diagnostic Testing**

**Laboratory Tests**

Routine laboratory tests are generally not needed for patients with isolated mild TBI in the acute setting, except for a bedside glucose test in patients with altered mental status and determination of the blood alcohol level in patients suspected of alcohol intoxication and head trauma. Suspicion of a systemic insult as the cause of the head trauma, such as when a diabetic patient sustains a MVC after losing consciousness from hypoglycemia, warrants directed testing for culprip conditions. Coagulation studies are indicated in patients with coagulopathies (eg, hemophilia, Von Willebrand disease), suspected liver disease, and those on anticoagulants. Ancillary laboratory tests that may provide useful information in the subsequent management of the patient include a urine toxicology screen, blood alcohol level, complete blood count, and electrolyte levels. In severe TBI patients, coagulation parameters (eg, platelet count) can indicate a worse prognosis.45

**Neuroimaging**

**Skull Radiography.** Skull radiography after head trauma rarely is indicated and has long been replaced by cranial computed tomography (CT), which is the cornerstone of imaging for acute head trauma. Although patients with clinical signs of skull fracture have a substantially increased incidence of intracranial lesions, numerous studies have shown that skull radiographs are neither sensitive nor specific for intracranial injury. When the clinical examination shows evidence of skull fractures, CT should be performed. Although plain skull radiographs were used in the past to localize missile fragments or ascertain penetration of the skull, CT also is the radiologic test of choice for penetrating head trauma.30 The bone windows of the CT scan can detect skull fractures (including basilar fractures). CT defines the precise location of the missile, its intracranial path, the presence of bone or missile fragments, extra-axial or intracerebral blood collections or other traumatic lesions, and pneumocephalus. Skull radiographs for adults with MTBI are not recommended.

**Computed Tomography.** Noncontrast CT of the head is the diagnostic standard for identifying intracranial injury in the ED. This scan delineates acute intra-axial and extra-axial bleeding, cerebral swelling, ischemic infarction caused by hypoxia after trauma, evidence of increased ICP, and pneumocephalus. It is sensitive for demonstrating mass effect, ventricular size and configuration, bone injuries, and acute hemorrhage, regardless of location (ie, parenchymal, subarachnoid, subdural, or epidural spaces).47 Follow-up CT should be performed if there is any clinical deterioration.

**Pneumocephalus.** This is often associated with missile wounds that penetrate the sinuses but can be caused by free air sucked into the penetration cavity behind the projectile. All tangential GSWs should be evaluated with a head CT scan secondary to the high incidence of associated intracranial injury.25 Angiography may be indicated to better discern location referable to key vascular structures. Pneumocephalus is also associated with open skull fractures.

**Epidural Hematoma.** On CT scan, an EDH appears hyperdense, biconvex, ovoid, and lenticular. The EDH does not usually extend beyond the dural attachments at the suture lines. The margins are sharply defined, and the hematoma usually bulges inward toward the brain (Fig. 34.7). EDHs of mixed density on CT may be actively bleeding. The temporoparietal region is the most likely site for an EDH. An EDH is usually unilateral, and 20% of patients have other intracranial lesions, usually SDHs or contusions. The deterioration of a patient who has an EDH from arterial bleeding can be rapid and dramatic.

A posterior fossa EDH is the most common traumatic mass lesion of the posterior fossa and accounts for 5% of EDHs. On CT scan, a posterior fossa EDH looks similar to other EDHs, but may cross the midline and extend above the tentorium to the supratentorial compartment (Fig. 34.8).

**Subdural Hematoma.** Unlike EDHs, SDHs often extend beyond the suture lines (Fig. 34.9). An SDH may follow the contour of the tentorium and be detected within the intrhemispheric fissure (Fig. 34.10). Many patients with an acute SDH also show CT evidence of intracerebral lesions contralateral to the SDH. A subacute SDH is symptomatic between 24 hours and 2 weeks after injury. It may appear hypodense or isodense on CT scans. Contrast increases the detection of isodense lesions. Patients complain of a headache, altered mental status, or focal deficits.

On a CT scan, a chronic SDH may appear isodense or hypodense to brain parenchyma. Indirect evidence of the lesion includes a midline shift, effacement of the ipsilateral cortical sulci, and ventricular compression. Contrast may increase the likelihood of identifying a chronic SDH that has become isodense. On a CT scan, blood of various ages is seen as a mixed-density lesion. On a magnetic resonance imaging (MRI) scan, a chronic SDH appears hyperdense.

Posterior fossa SDHs are caused by occipital trauma and, on a CT scan, they do not cross the midline or extend above the tentorium. The outcome of a posterior SDH is very poor.

**Traumatic Subarachnoid Hemorrhage.** A noncontrast CT scan allows the diagnosis to be made, with increased density noted within the basilar cisterns. Blood can also be seen within the intrhemispheric fissures and sulci. The amount of blood within the SAH correlates directly with the outcome and inversely with the presenting GCS score.
Subdural Hygroma. On CT, SDHGs appear crescent shaped in the extra-axial space; the density is the same as that of CSF. Bilateral SDHGs are common.

Diffuse Axonal Injury Traumatic Axonal Injury. Diffuse TAI is the most common CT finding after severe head trauma, estimated to occur in over 50% of all comatose head trauma patients. However, in milder cases, there is no specific acute focal traumatic lesion noted on a head CT scan or on structural MRI scan. Occasionally, small petechial hemorrhages in proximity to the third ventricle and within the white matter of the corpus callosum or internal capsule of the brainstem are detected. An intraventricular hemorrhage on the initial CT scan has been reported to be an early predictor of DAI lesions in the corpus callosum on MRI. Although histopathologic examination of postmortem brain tissue is the gold standard for diagnosing TAI, advanced MRI neuroimaging techniques, such as diffusion tensor imaging (DTI), may help assess white matter integrity (Fig. 34.11).

Cerebral Contusions. Non–contrast-enhanced CT is the best diagnostic test to discover contusions in the early posttraumatic period. These appear heterogeneous and irregular because of mixed regions of hemorrhage, necrosis, and infarction. Often, the surrounding edematous tissue appears hypodense. By posttrauma days 3 and 4, the blood located within the contusions has begun to degrade, and structural MRI becomes more useful.

Intracerebral Hematoma. An intracerebral hematoma may be detected on the first CT scan immediately after injury but often is not seen for several hours or days. Unlike contusions, ICHs are usually deep in the brain tissue and often become well demarcated over time. On CT scan, an ICH appears as a well-defined hyperdense homogeneous area of hemorrhage (Fig. 34.12).

Traumatic Intracerebellar Hematoma. Often, these patients have an associated skull fracture, posterior fossa EDH or SDH, or supratentorial contrecoup hematomas and contusions.

Cerebral Edema. On CT scans, diffuse edema manifests as bilateral compression of the ventricles, loss of definition of the cortical sulci, or effacement of the basal cisterns (Fig. 34.13). Focal
CHAPTER 34  Head Trauma

hematoma, and the presence of intraventricular blood and/or traumatic subarachnoid hemorrhage (Box 34.3).

Management

Out-of-Hospital Care

The out-of-hospital management of the head-injured patient should focus on preventing or minimizing secondary brain injury.

edema adjacent to traumatic mass lesions demonstrates decreased density on CT scans compared with normal tissue.

Rotterdam Computed Tomography Score. The Rotterdam score was developed to determine the risk for mortality in traumatic brain injury. It is based on initial noncontrast CT findings of basal cistern compression, midline shift, presence of an epidural hematoma, and the presence of intraventricular blood and/or traumatic subarachnoid hemorrhage (Box 34.3).

Fig. 34.11. Sequential scan findings in severe traumatic brain injury (TBI) with traumatic axonal injury (TAI). In the ED, on initial day of injury (DOI) CT imaging, the scan on the far left shows primarily generalized edema but, by 7 hours, distinct intraparenchymal hemorrhages appear, particularly within the left temporal lobe. By 3 months postinjury, TAI and intraparenchymal hemorrhages result in massive degenerative effects, reflected in temporal horn dilation and markedly abnormal white matter signal differences throughout the temporal and occipital lobes on the fluid-attenuated inversion recovery (FLAIR) sequence. Temporal horn dilation is also evident in the right temporal lobe as well, reflective of the generalized atrophy. The loss of white matter integrity is more distinctly observed using diffusion tensor imaging (DTI), where there is no coherent direction noted in the left temporal region; even though the right temporal lobe exhibits atrophic changes, the inferior occipitotemporal fasciculus (arrow) is distinctly visible. The control MRI scan is a T1 image showing symmetric temporal lobe morphology with the normal slitlike appearance of the temporal horns. (Adapted from Bigler ED, Maxwell WL: Neuropathology of mild traumatic brain injury: relationship to neuroimaging findings. Brain Imaging Behav 6:108–136, 2012.)

Fig. 34.12. Non–contrast-enhanced CT scan of right occipital and temporal intracerebral hematomas, surrounded by mild edema and hemorrhagic contusion. A small, intrahemispheric, subdural hematoma is visible in the posterior interhemispheric fissure. Midline shift is obvious. A ventriculostomy has been placed and is visible as high-density image within the ventricles.

Fig. 34.13. Non–contrast-enhanced CT scan showing diffuse cerebral edema. Loss of gray-white differentiation in the brain parenchyma is present. Bilateral compression of the ventricles has occurred, with loss of cortical sulci.
The two major systemic insults are hypotension and hypoxia. Interventions should be aimed at maintenance of oxygenation and prevention of hypotension through directed fluid resuscitation and control of hemorrhage.

**Airway.** Controversy exists regarding the benefits of out-of-hospital intubations in patients with brain injuries. In systems with short transport times, and in patients in whom an oxygen saturation more than 90% can be maintained with supplemental oxygen, field intubation is of questionable benefit and may potentially lead to worse outcomes. Although unsuccessful attempts at field intubations may add to out-of-hospital time and increase the risk of aspiration or hypoxia, patients who are hypoxic or unable to maintain their airway have improved outcomes in terms of mortality and neurologic outcome with field intubation.

The ultimate goal in the field is to prevent or minimize hypoxia. Out-of-hospital airway protocols balance the risks of emergency intubation in an uncontrolled setting with the need to secure an at-risk airway and prevent hypoxia. If oxygenation can be maintained and transport time is short (most urban settings), definitive airway management should be delayed until arrival in the ED. If endotracheal intubation is undertaken in the field, it should be performed by skilled practitioners with a rigorous quality assurance program and continuous provider training. All advanced airway placement should be confirmed with quantitative end tidal capnography (ETCO₂), which dramatically improves the detection of improperly placed airway devices and inadvertent hyperventilation by field providers. Prehospital endotracheal intubation is associated with poorer prognosis in children and should be avoided in this population (see Chapter 165).

**Hypotension.** Avoiding and managing hypotension are critical elements of the prehospital treatment of the head-injured patient. The secondary survey of the head-injured patient should include a search for external signs of head trauma. Scalp lacerations may bleed a large volume into a bulky dressing, and a less bulky dressing should be used with firm constant manual pressure applied to avoid excessive blood loss. Any other ongoing external hemorrhage should be expeditiously addressed and controlled. Although permissive hypotension may be beneficial in some trauma patients, it is detrimental in the setting of brain injury.

**Agitation.** Many severely head-injured patients are initially combative or agitated. Transporting an agitated patient who is fighting against physical restraints may exacerbate physical injury, cause an increase in ICP, and interfere with appropriate stabilization and management. Management of agitation in the out-of-hospital setting mirrors that used in the ED, as described below.

**Emergency Department Management**

**General.** In the ED phase of patients with severe head trauma, management is in accordance with ATLS (Advanced Trauma Life Support) protocols. Monitoring of vital signs should be continuous, such as respiratory status (pulse oximetry, capnography), heart rate, blood pressure, and temperature. Tetanus status should be determined and prophylaxis given, as appropriate. Pregnancy status in women of childbearing age should be verified.

**Airway.** Primary airway compromise in the setting of head trauma may result from craniofacial or neck trauma, bleeding, or vomiting. Secondary airway compromise may also result from brain injury, as in the case of loss of brainstem reflexes, patient agitation, severe systemic hypotension, or alterations in mental status. In either case, the airway should be secured early to protect against aspiration and prevent secondary brain injury as a result of hypoxia or hypercarbia.

If possible, a rapid but detailed neurologic examination should be performed before the patient is given any sedative or neuromuscular blocking agent. This focused examination includes careful recording of the elements of the GCS, characterization of movement of all four extremities (to command, purposeful response to pain, localizing pain, withdrawal, posturing), tone, and pupillary reflexes. These elements are essential in correlating CT findings with clinical injury and are also useful in following the patient’s progression. The drug selection and technique of intubation for the head-injured patient is discussed in Chapter 1.

**Hypotension.** If hypotension is detected at any time in the emergent management of a potentially brain-injured patient, a cause other than the brain injury should be sought (see Chapter 33). Systemic hypotension has profound implications for neurologic outcomes. In fact, a single episode of hypotension doubles mortality risk. As such, fluids or blood transfusion should be delivered to maintain a SBP of at least 90 mm Hg. Maintaining the SBP above 100 mm Hg may be considered to decrease mortality and improve outcome.

**Brain-Directed Hyperosmolar Therapy.** If there are signs of impending herniation syndrome, such as deepening coma, a newly asymmetric pupil, or other substantially diminishing neurologic parameters, we recommend the use of osmotic diuretics, such as mannitol or hypertonic saline (HTS). Mannitol is the time-honored mainstay for the control of elevated ICP in acute severe TBI. Mannitol (0.25–1 g/kg) can effectively reduce cerebral edema by producing an osmotic gradient that reduces brain volume and provides increased space for an expanding hematoma or brain swelling. The osmotic effects of mannitol occur within minutes and peak approximately 60 minutes after bolus administration. The ICP-lowering effects of a single bolus may last for 6 to 8 hours. Mannitol is also an effective volume expander and, in the presence of hypovolemic hypotension, may aid in maintaining

it does not improve mortality. Proposed benefits of HTS include reducing secondary injury through effects on cellular modulation, decreasing cerebral edema, improving peripheral perfusion, and decreasing ICP through vasoregulatory mechanisms and upregulation of proinflammatory and prothrombotic mediators. Numerous clinical studies have demonstrated that HTS can significantly reduce ICP; however, the total number of enrolled patients in these trials is small, and interpretation is complicated by variation in protocols, HTS concentration, and rate of administration.10

Among patients with severe TBI not in hypovolemic shock, initial resuscitation with hypertonic saline or hypertonic saline-dextran, compared with normal saline, was found not to result in superior 6-month neurologic outcome or survival.60,61 Mannitol can produce renal failure or hypotension if given in large doses. It may also induce a paradoxical effect of increased bleeding into a traumatic lesion by decompressing the tamponade effect of a hematoma. Potential adverse events associated with HTS include renal failure, central pontine myelinolysis, and rebound ICP elevation.62 Osmotic therapy should be guided by findings on ICP monitoring. Prior to initiation of such monitoring, brain-directed osmotic therapies should be reserved for patients with signs of transtorial herniation or progressive neurologic deterioration not attributable to extracranial causes.63

Osmolar therapy with mannitol or hypertonic saline can draw water across an intact BBB and thereby lower ICP. Mannitol, 0.25 to 1 g/kg, is given every 6 hours, up to a serum osmolality of 320 mOsm/kg. Treatment with 30 mL of 23.4% HTS appears to be at least as effective as mannitol at lowering ICP rapidly and reversing herniation, although a central line is necessary for safe administration. Hypertonic saline (23.4%), 30 to 60 mL, can be given every 6 hours, up to a maximum serum sodium level of 160 mEq/L. Because it is a potent diuretic, mannitol is preferred in cases of fluid overload, whereas HTS can be used as a resuscitative fluid; a 3% or 23.4% solution can be used.62

**Hyperventilation.** Under normal conditions, Paco₂ is the most powerful determinant of CBF and, between a range of 20 and 80 mm Hg, CBF is linearly responsive to PaCO₂. Formally, so-called therapeutic hyperventilation was recommended as a method to reduce ICP. Unfortunately, however, this reduction in ICP is accomplished by reducing CBF, which is important in meeting the brain’s metabolic demands. A low Paco₂, therefore, and the resulting low CBF, may result in cerebral ischemia, whereas high Paco₂ levels can result in cerebral hyperemia and high ICP. Normal ventilation is currently the goal for severe TBI patients in the absence of cerebral herniation, and Paco₂ is maintained in the normal range, from 35 to 45 mm Hg.63 In the case of life-threatening cerebral herniation or significant ICP elevation, therapeutic hyperventilation is appropriate only as a short-term intervention, bridging to more definitive therapy (eg, craniectomy). Therefore, hyperventilation is recommended only as a temporizing measure for the reduction of elevated ICP and should not be used for routine management or prophylaxis. Hyperventilation should be avoided during the first 24 hours after injury when CBF is often critically reduced. If hyperventilation is used, jugular venous oxygen saturation (SjO₂) or brain tissue O₂ partial pressure (BtpO₂) measurements are recommended to monitor oxygen delivery.62,64 The neurologic effects of hypocapnia are illustrated in Fig. 34.15.

**Cranial Decompression.** In patients with impending herniation who do not respond to osmotic therapy and hyperventilation, particularly those with a history of so-called talk and deteriorate after head trauma, emergency cranial decompression may temporarily reverse or arrest the herniation syndrome.65,66 Emergency trephination may allow enough time for a patient to
undergo a formal craniotomy in the operating room. However, most patients presenting unconscious have sustained diffuse massive brain injury, with no focal lesion amenable to emergency decompression. Patients with erratic or absent respiratory effort, bilateral fixed and dilated pupils, no spontaneous eye movements, and decerebrate posturing do not benefit from emergent burr holes. Furthermore, placement of a burr hole is a blind invasive procedure, and the chances of localizing the expanding lesions are uncertain. Trephination should be undertaken only after confirmation of an extradural collection by neuroimaging and only by, or under the guidance of, an emergency clinician with specific training.

Decompressive craniectomy (DC) is the surgical removal of the skull bone and has been performed for the purpose of relieving elevated ICP, with outcome improvement in some TBI patients. Bifrontal DC has been used in severe TBI patients with diffuse injury (without mass lesions) who have ICP elevation to more than 20 mm Hg for more than 15 minutes within a 1-hour period, refractory to first-tier therapies. There is no evidence for improved outcome, as measured by the Glasgow Outcome Scale-Extended (GOS-E) score, at 6 months postinjury. However, this procedure has been demonstrated to reduce ICP and to minimize days in the intensive care unit (ICU). A large frontotemporoparietal DC (not <12 × 15 cm or 15 cm diameter) is recommended over a small frontotemporoparietal DC for reduced mortality and improved neurologic outcomes in patients with severe TBI.

Hemostatic Agents. Patients taking warfarin may be managed with prothrombin complex concentrate, fresh-frozen plasma, or vitamin K. Reversal of warfarin-associated anticoagulation is discussed in Chapter 114. There is inadequate evidence to support the routine use of platelet transfusion for intracranial hemorrhage for patients taking preinjury antiplatelet medications.
(eg, aspirin, clopidogrel).79 Idarucizumab, a reversal agent against dabigatran, is approved for emergency surgery and urgent procedures or in life-threatening or uncontrolled bleeding. Although studies are lacking in the setting of TBI, when significant intracranial bleeding is identified in patients with acute TBI who are taking dabigatran, we recommend reversal with idarucizumab. The recommended dose for idarucizumab is 5 g (2.5 g/vial) administered intravenously as two consecutive 2.5-g infusions or as a bolus injection by injecting both vials consecutively, one after another, via syringe.

Recombinant factor VIIa (rFVIIa) is a hemostatic agent that was originally developed to treat bleeding in hemophiliacs. Limited military experience led to interest in the use of rFVIIa for traumatic intracerebral hemorrhage as well.1,12 However, results of clinical trials are mixed, and there has been no convincing evidence of benefit for this expensive agent in traumatic intracranial hemorrhage in the absence of preexisting coagulopathy. We do not recommend routine use of rFVIIa for patients with traumatic intracranial hemorrhage.7,9

When given early after injury (within 3 hours), tranexamic acid (TXA) has demonstrated benefit in trauma with hemorrhage without increasing the risk of adverse events.74,75 The use of TXA is discussed in Chapter 33. Tranexamic acid is of no benefit for patients with isolated head trauma or head trauma without significant systemic hemorrhage and may even be harmful. TXA should not be used in this population.

Induced Hypothermia. Hyperpyrexia worsens outcome after severe TBI, and guidelines emphasize maintaining normothermia with antipyretic medications and cooling devices.34 Induced therapeutic hypothermia has been proposed to decrease ICP, including reducing proinflammatory cytokines and stabilizing the BBB. However, the routine use of hypothermia for the treatment of TBI has met with mixed results in adult and pediatric populations.77-79 Although hypothermia remains a significant area of research and promise for patients with severe and moderate TBI, the available scientific evidence is inconclusive with regard to improved mortality or morbidity.80 Some studies have shown the potential for benefit,7 but a recent randomized trial has shown that therapeutic hypothermia for severe TBI does not improve the neurologic outcomes or risk of mortality compared with strict temperature control.78 Similarly, in another randomized trial in patients with an elevated ICP of more than 20 mm Hg, therapeutic hypothermia plus standard care to reduce ICP id not result in outcomes better than those with standard care alone.8 We do not recommend the routine use of therapeutic hypothermia for the treatment of TBI.

Seizure Prophylaxis. Acute symptomatic seizures may occur as a result of severe traumatic brain injury (TBI). Such PTs are classified as early when they occur within 7 days of injury or late when they occur after 7 days following injury. Posttraumatic epilepsy (PTE) is defined as recurrent seizures more than 7 days following injury. Up to 12% of all patients who sustain blunt head trauma and 50% of those with penetrating head trauma develop early PTs.46,82 Although the occurrence of seizures in the immediate posttrauma period is not predictive of future epilepsy, early seizures can cause hypoxia, hypercarbia, release of excitatory neurotransmitters, and increased ICP, potentially worsening secondary brain injury.

Prophylactic use of phenytoin or valproate is not recommended for preventing late PTs, but phenytoin is recommended to decrease the incidence of early PTs (within 7 days of injury), when the overall benefit is thought to outweigh the risk of complications associated with such treatment.10,84 Early PTs have not been associated with worse outcomes,10 but the use of prophylactic anticonvulsants in penetrating brain injuries is recommended for 7 days postinjury.16 There is insufficient evidence to recommend levetiracetam over phenytoin; we recommend phenytoin for early PTs and toxicity.15

If the patient is actively seizing, benzodiazepines are administered as effective, rapid-acting, first-line anticonvulsants. Lorazepam (0.05–0.1 mg/kg IV) is the preferred agent for aborting seizures because of its high effectiveness and prolonged duration of action. Diazepam (0.1–0.2 mg/kg) or midazolam (0.05–0.1 mg/kg) is an effective alternative. For long-term anticonvulsant activity, phenytoin (18–20 mg/kg IV) or fosphenytoin (phenytoin equivalents, 15–18 mg/kg) can be given. Fosphenytoin has the advantages of rapid administration, smaller volume of fluid for the dose delivered, and less potential for hypotension than phenytoin.

Antibiotic Prophylaxis. Although the practice was once widespread, there is no evidence to support the use of antibiotic prophylaxis for the prevention of meningitis or other infection in patients with blunt basilar skull fractures, with or without evidence of CSF leakage.84-85 Penetrating brain injury, however, is a different matter. Contamination with skin, bone, hair, and tissue occurs and may be widespread when there is cavitation caused by the missile as it passes through the brain.86 Evidence supports the use of intravenous (IV) prophylactic, broad-spectrum antibiotics to cover for staphylococci, gram-negative bacilli, and anaerobes for penetrating craniocerebral trauma. Although there are several potential antibiotic regimens, a combination of vancomycin, 1 g bid, gentamicin, 80 mg tid, and metronidazole, 500 mg qid, will provide adequate coverage.86,87

Patients undergoing ICP monitoring are reported to have related infection rates as high as 27%.88 For external ventricular drains (EVDs), routine catheter exchanges has been replaced by attention to proper care during insertion, CSF sampling techniques and, in some cases, prophylactic IV antibiotics. In a single-institution study, bundle implementation (including hand hygiene, prophylactic antibiotics, sterile technique, hair removal for dressing adherence, skin preparation using iodine and isopropyl alcohol, full surgical attire for the surgeon and other bedside providers), together with an antimicrobial-impregnated catheter, dramatically decreased EVD-related infections. We recommend training and situational awareness of best practices for infection control, assisted by checklists. However, there is insufficient evidence at this time to recommend antibiotic-impregnated EVDs for minimizing infection.

Other Therapies Corticosteroids. Corticosteroids have no benefit for patients with head trauma, and in fact demonstrate an increase in adverse events, including infection, gastrointestinal bleeding and mortality. In patients with severe TBI, high-dose methylprednisolone is associated with increased mortality and is contraindicated.16

Barbiturates. Barbiturate therapy has historically been used in severely brain-injured patients to reduce cerebral metabolic demands of the injured brain tissue and reduce elevated ICP. However, barbiturates also can cause a decrease in SBP. Compared with placebo, barbiturates offer no mortality benefit; furthermore, any benefit of decrease in ICP is offset by the risk of hypotension.89 The only remaining value of barbiturates in TBI is the use of high-dose barbiturate therapy to control elevated ICP refractory to maximum standard medical and surgical treatment. Hemodynamic stability is essential before and during barbiturate therapy.10 Prophylactic administration of barbiturates to induce burst suppression measured by electroencephalography is not recommended.

Monitoring of Intracranial Pressure and Cerebral Spinal Fluid Drainage. Management of severe TBI patients using information from ICP monitoring is recommended to reduce
in-hospital and 2-week postinjury mortality. However, management of EVD systems in patients with severe TBI remains a controversial topic. An EVD in a closed position allows for monitoring of ICP, whereas in an open position drainage of CSF can occur. Practice patterns regarding whether the EVD should be maintained in a closed or open position vary widely based on a number of variables, including patient age, institutional resources, and physician preferences. Continuous CSF drainage is a relatively common practice in the pediatric population. In adults, there is variability in practice with three options: (1) continuously monitoring ICP and only intermittently draining for ICP elevations; (2) intermittently monitoring ICP with continuous drainage of CSF; or (3) continuously monitoring ICP with continuous drainage of CSF. An EVD system seared at the midbrain with continuous drainage of CSF may be considered to lower ICP burden more effectively than intermittent use. The use of CSF drainage to lower ICP in patients with an initial GCS less than 6 during the first 12 hours after injury may be considered.

Glucose Control and Nutrition. Hyperglycemia and hypoglycemia are associated with worsened outcomes following a severe TBI, but the optimal glucose target and best treatment regimen is yet to be determined. The complex interaction of the body with nutritional support is magnified during illness, particularly after severe TBI. Severe TBI is associated with increased energy expenditure early after injury. Guidelines recommend feeding patients to attain basal caloric replacement, at least by the fifth day and, at most, by the seventh day postinjury is recommended to decrease mortality. Furthermore, transgastric jejunal feeding is recommended to reduce the incidence of ventilator-associated pneumonia.

Erythropoietin. In a recent multicenter randomized controlled trial of patients with moderate to severe TBI, erythropoietin did not reduce the number of patients with severe neurologic dysfunction or increase the incidence of deep venous thrombosis of the lower limbs. There was no effect on mortality at 6 months. It is not recommended for use at this time.

Progesterone. Progesterone has been shown to improve neurologic outcome in early-phase trials involving patients with TBI. In a double-blind, multicenter clinical trial, progesterone was administered to TBI patients with moderate to severe TBI within 4 hours of injury. Progesterone did not improve outcomes in patients with TBI over placebo. These findings are consistent with a recent meta-analysis. Progesterone is not recommended for treatment of TBI.

Hyperbaric Oxygen Therapy. Hyperbaric oxygen therapy follows severe, acute TBI provides the injured brain with an increased partial pressure of oxygen and theoretically reduces cerebral edema. However, although the pooled results of several small studies have suggested some benefit in terms of survival, the clinical significance is questionable. Thus, the use of hyperbaric oxygen therapy for the treatment of TBI injury cannot be recommended.

Management of Specific Injuries

Scalp Wounds. If blood loss is brisk, rapid hemostasis is a priority. Initially, hemostasis may be achieved by the application of a temporary, tight pressure dressing, allowing prompt attention to other priorities. Alternatively, a stapler may be used to staple the scalp laceration rapidly to control bleeding. The wound later can be reopened for proper irrigation and reclosure. Other methods to achieve hemostasis include direct digital compression of the bleeding vessel against the skull, infiltration of the wound edges with lidocaine plus epinephrine, and clamping or ligation of identified bleeding vessels. The best approach is repair with sutures or staples because the closure will assist in tamponade. In stable patients, closure of the wound, after proper débridement and irrigation, is the most effective way to stop a bleeding scalp laceration and prevent the tissue crush injury that may occur if other compressive methods are used for too long.

Once hemostasis is obtained, the wound should be irrigated to rinse away any debris. The emissary vessels of the subgaleal layer of the scalp drain directly into the diploe veins of the skull. These in turn drain into the venous sinuses. Contaminated or infected scalp wounds, therefore, have the potential to cause serious intracranial infections. Blood clots and other debris should be removed and the galea and underlying cranium palpated to detect any remaining debris, disruptions, or bone step-offs. Shear injuries to the scalp may deposit contaminants at sites distant from the apparent injury. The complexity of stellate lacerations often interferes with thorough inspection and débridement, making them particularly susceptible to infection. Digital exploration of a scalp wound should be performed gently; if done too vigorously, comminuted or depressed bone pieces may be depressed further.

It is easy to confuse a disruption in the peristeum with a skull fracture. The base of the laceration should therefore be directly visualized. Clipping away a small area of hair parallel to the edges of the wound may facilitate this. Alternatively, an antibiotic ointment can be applied to the hair immediately surrounding the wound and used to plaster the hair away from the injury site. If hair is accidentally embedded within the repaired laceration, it can delay healing by producing an inflammatory reaction or by serving as a nidus of infection. If the laceration begins on the forehead and extends upward beyond the hairline, surrounding hair should not be removed. Removal obliterates a useful landmark for cosmetic closure and may result in malalignment of the two laceration edges.

Several studies have evaluated the use of staples versus sutures to close scalp lacerations that do not involve the galea. For adult and pediatric scalp lacerations that begin beyond the hairline, staples have been shown to be cheaper, take less time, and have the same outcome than sutures if used in the appropriate manner. However, staples cannot be used to close the galea and may not be effective alone when hemostasis is a problem. Large lacerations of the galea are closed to prevent the edges of the wound from pulling apart as the muscles within the galea contract. The skin, dermis, and galea can usually be repaired in a single layer with interrupted or vertical mattress sutures of 3-0 nylon or polypropylene. Recently, an alternative method of scalp laceration closure has been described, in which bundles of the patient’s hair on each side of the wound are twisted together and then secured with tissue glue. This may provide another method of effective repair and prevent the need to remove the closure material after the wound has healed, particularly in the pediatric population. Because of the rich blood supply of the scalp, even very large scalp avulsions may remain viable. If the avulsion remains attached to the rest of the scalp by a tissue bridge, it should be reattached to the surrounding tissue. If the avulsion is completely detached from the scalp, it should be treated as any other amputated part and reimplemented as soon as possible.

Scalp abrasions are often contaminated with pieces of dirt or other debris. The wound should be cleaned as thoroughly as possible and inspected for puncture wounds or other areas that penetrate beyond the superficial layers of the skin to ensure the removal of unsuspected foreign bodies. A careful inspection often reveals a small scalp laceration within the abraded area. Systemic antibiotics are usually not needed for carefully managed scalp wounds because rapid healing is facilitated by the rich blood supply of the scalp. However, special consideration may be given to large or highly contaminated wounds, bite wounds, and immuno-compromised patients.

Skull Fractures. A noncontrast head CT scan with bone windows has become the imaging modality of choice for patients
with suspected skull fractures or to identify intracranial foreign bodies. Plain radiographs can be useful when CT is not available.

**Linear Fractures.** Linear skull fractures are clinically important if they cross the middle meningeal groove or major venous dural sinuses; they can disrupt these vascular structures and cause the formation of EDHs. No specific intervention is necessary for linear skull fractures if a noncontrast CT scan reveals no underlying brain injury. Patients with no evidence of intracranial injury on CT and no other significant extracranial injuries should be observed in the ED for 4 to 6 hours prior to discharge. If there is any suspicion or clinical evidence of brain injury, patients should be admitted for observation. Those with intracranial injuries should have an emergent neurosurgical consultation. Patients with simple linear skull fractures may demonstrate concussive symptoms or other evidence of mild TBI and should be provided appropriate discharge instructions (see later, “Mild Traumatic Brain Injury: Disposition”).

**Depressed Fractures.** When a depressed fracture occurs, traumatic impact drives the bone piece below the plane of the skull. The edges of the depressed portion of skull may become locked underneath the adjacent intact bone and fail to reduce into their anatomic position. As a result, the depressed piece of bone can penetrate tissue and lacerate the dura. Fractures in which the free piece of bone is depressed deeper than the adjacent inner table of the skull require surgical elevation. Depressed skull fractures are usually open fractures with disruption of the galea, which can often be felt with palpation of the skull. However, this examination should be done cautiously to avoid driving a depressed bone fragment deeper into the cranium. The clinical examination for a depressed skull fracture may be misleading. The mobility of the scalp can result in nonalignment of the fracture with an overlying scalp laceration. As a result, the skull underlying the laceration may be normal, with the depressed area several centimeters away. Scalp swelling may interfere with the physical examination findings and hide any palpable bone defects.

Depressed fractures may be difficult to visualize on plain skull radiographs. The free piece of bone demonstrates increased or double density because it often overlaps the nonfractured bone, or it is rotated from the rest of the adjacent cranium. Tangential views of the skull may increase the ability to visualize the fracture. However, CT scanning with bone windows, if available, remains the imaging modality of choice.

An open depressed skull fracture, as well as any type of penetrating skull injury, increases the risk for developing intracranial and meningeal infection and seizures and should receive prophylaxis. Patients with depressed skull fractures should be admitted for continued observation. Patients with open (compound) cranial fractures depressed greater than the thickness of the cranium should undergo operative intervention to prevent infection. They may be treated nonoperatively if there is no clinical or radiographic evidence of dural penetration, significant intracranial hematoma, depression greater than 1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination. Nonoperative management of closed (simple) depressed cranial fractures is a treatment option. For all open depressed skull fractures, we suggest that prophylactic antibiotics be given for 5 to 7 days to prevent the risk of subsequent CNS infection. Suggested antibiotics are identical to those for penetrating head trauma.

**Basilar Skull Fractures.** Basilar fractures are the result of considerable impact force and are highly associated with underlying brain injury. Emergency clinicians should be suspicious of an epidural hematoma in patients with a temporal bone basilar skull fracture. All patients with basilar skull fractures should be admitted for observation, regardless of the need for surgical intervention. A systematic review and meta-analysis of antibiotic prophylaxis following basilar skull fracture has concluded that routine prophylaxis is not supported by the available evidence, whether or not there is evidence of CSF leakage. We do not recommend routine antibiotics for basilar skull fractures unless the patient is immunocompromised. Most CSF leaks resolve spontaneously within 1 week, with no complications. If the leak persists beyond 7 days, the incidence of bacterial meningitis increases significantly; prophylactic antibiotics should be given in such cases. Antibiotic selection is identical to that for penetrating head trauma. If a patient with a previously diagnosed CSF leak returns to the ED later with fever, the diagnosis of meningitis should be strongly suspected and appropriate evaluation (ie, lumbar puncture) and antibiotic treatment initiated immediately. Treatment of posttraumatic meningitis is discussed in Chapter 99.

**Extra-Axial Lesions.**

**Epidural Hematoma.** Expert consensus guidelines support rapid surgical evacuation for any patient who has mass effect on a CT scan or progressive neurologic deterioration. Indications for urgent surgical evacuation include epidural hematomas larger than 3 cm, regardless of the patient’s GCS score, as well as comatose patients with an acute EDH and anisocoria on pupillary examination. For patients with acute EDH who are awake and have no focal neurologic deficits, nonsurgical management is based on the size of the hematoma (>3 cm²), thickness of the clot (<15 mm), and degree of midline shift (<5 mm). In those managed nonoperatively, close neurologic observation in a neurological center is required, and the first repeat CT scan should be obtained within 6 to 8 hours postinjury.

**Subdural Hematoma.** Because of associated brain injury caused by the SDH, the delay in clinical signs and symptoms, and the more advanced mean age of the at-risk population, the mortality associated with SDH is much higher than that associated with EDH. Pupil inequality, motor deficit, and other signs consistent with increased brain swelling may be present on the initial examination. If the patient is deeply comatose at presentation, with flaccidity and without signs of brainstem activity, he or she may best be served by simply providing supportive care. Subsequent management decisions should be discussed with the patient’s family and attending neurosurgeon. A small SDH (only a few millimeters thick at its widest point on CT scan) often is amenable to serial observations of the patient’s status and appearance of the SDH on CT scan. Even a small SDH may be accompanied by extensive brain tissue damage that can cause an increase in ICP sufficient to precipitate a herniation syndrome. Indications for surgical evacuation include acute SDHs with a thickness more than 10 mm or a midline shift of more than 5 mm on a CT scan, regardless of the patient’s GCS score. Other parameters for surgical evacuation include a worsening GCS score (≥2 points from the time of injury to hospital admission) in comatose patients, asymmetric or fixed and dilated pupils, and persistent elevation in ICP. Most patients with subacute SDH require surgical evacuation of the lesion.

The treatment of chronic SDHs is controversial. Symptomatic chronic SDHs require surgical evacuation. Most patients have a good outcome after surgery. Overall, the mortality from surgically drained chronic SDH approaches 5%, with decreased survival in older adults.

**Traumatic Subarachnoid Hemorrhage.** If there is no other brain injury, ISAH does not generally carry a poor prognosis. The most serious complication of ISAH is worsening of cerebral vasospasm, which may be severe enough to induce cerebral ischemia. Posttraumatic vasospasm is common, occurring approximately 48 hours after injury and persisting for up to 2 weeks. Vasospasm following TBI is characterized by a different time course, duration, and associated profile of risk factors than those of aneurysmal SAH (aSAH). Although, no treatments have been shown to affect outcomes conclusively in tSAH, calcium channel
blocks, such as nimodipine and nicardipine, have been used in the acute ICU setting to prevent or reduce vasospasm after tSAH.\textsuperscript{105} However, we do not recommend the routine use of calcium channel blockers in tSAH. Patients with severe TBI and large amounts of SAH may benefit from serial noninvasive monitoring and institution of therapy in the setting of radiographic or clinical deterioration.

**Subdural Hygroma.** If SDHGs are asymptomatic, observation is reasonable. Otherwise, they are surgically evacuated. Mortality approaches 20% and appears to depend on the severity of other intracranial injury.\textsuperscript{101}

**Intra-Axial Lesions**

**Cerebral Contusion.** In one series of patients with brain contusions who initially received conservative treatment, 45% had significant progression on CT, and 19% required surgical intervention.\textsuperscript{106} Patients with lower GCS scores and larger cerebral contusions are at higher risk for hemorrhagic progression and the need for delayed surgical decompression.\textsuperscript{107} Hemorrhagic progression of a contusion generally occurs within the first 12 hours, but may occur as late as 3 to 4 days after head trauma. Small contusions that progress are usually clinically silent and are unlikely to require surgical decompression.

**Intracerebral Hematoma.** Many patients with an ICH require emergent intervention or surgery to lower elevated ICP. Mortality is low in patients who are conscious before surgery, whereas in unconscious patients, mortality approaches 45%. ICHs that bleed into the ventricles or cerebellum also carry a high mortality rate.

**Intracerebellar Hematoma.** Acute management should first address the most clinically significant lesion. Mortality from isolated traumatic intracerebellar hematoma is very high. Emergent neurosurgical consultation is indicated.

**Complications and Outcome**

**Seizures**

PTSs are classified as early when they occur within 7 days of injury or late when they occur after 7 days following injury. PTE is defined as recurrent seizures more than 7 days following injury. In patients with severe TBI, the rate of a clinical PTS may be as high as 12%, whereas that of subclinical seizures detected on electroencephalography may be as high as 20% to 25%.\textsuperscript{108} The risk factors for early PTS include GCS score of 8 or lower, immediate seizures, posttraumatic amnesia lasting longer than 30 minutes, linear or depressed skull fracture, penetrating head injury, subdural, epidural, or intracerebral hematoma, cortical contusion, age 65 years or younger, or chronic alcoholism.\textsuperscript{82} Rates of PTE are substantially higher than the risk of developing epilepsy in the general population. The risk factors for PTE include severe TBI, early PTSs prior to discharge, acute intracerebral hematoma or cortical contusion, posttraumatic amnesia lasting longer than 24 hours, age older than 65 years, and premorbid history of depression.\textsuperscript{82}

Early PTSs, within 24 hours of injury, are usually brief and are probably caused by transient mechanical and neurochemical changes within the brain. In the 24 to 48 hours after trauma, seizures are caused by worsening cerebral edema, small hemorrhages, or penetrating injuries. PTSs are common in children and can be precipitated by MTBI but are more common in moderate and severe TBI.\textsuperscript{100,104} Acute PTS prophylaxis in the ED is recommended for preventing brain injury.\textsuperscript{46,105} Prophylactic use of phenytoin or valproate is not recommended for preventing late PTS from a nonpenetrating injury. Phenytoin is recommended to decrease the incidence of early PTS (within 7 days of injury), when the overall benefit is thought to outweigh the complications associated with such treatment. However, early PTSs have not been associated with worse outcomes.\textsuperscript{108} Newer agents, such as levetiracetam, have been assessed for this purpose as well.\textsuperscript{106} However, at present, there is insufficient evidence to recommend levetiracetam over phenytoin regarding efficacy for preventing early PTSs and toxicity.\textsuperscript{108} The decision to maintain the head trauma patient on long-term anticonvulsant therapy during the recovery period depends on the patient’s subsequent course. Long-term seizure prophylaxis is not indicated for all patients who have had PTSs in the acute or subacute period.\textsuperscript{109} Prophylactic anticonvulsants are not recommended to prevent late PTSs.\textsuperscript{10,107,108}

**Central Nervous System Infections**

**Meningitis After Basilar Fractures.** Posttraumatic meningitis is caused by a variety of microbes, depending on the portal of bacterial entry. Patients have typical signs and symptoms of meningitis, including fever, altered mental status, and occasional focal neurologic signs. In patients with a CSF leak after basilar fracture, early meningitis (ie, within 3 days of injury) is usually caused by pneumococci. Treatment of posttraumatic meningitis is discussed in Chapter 99.

**Brain Abscess.** Brain abscesses develop infrequently after penetrating missile injuries to the head. Abscesses can also develop after open depressed skull fractures if bone fragments are not removed or as a postoperative complication. Posttraumatic CSF fistulae and fractures that disrupt air-filled sinuses predispose to the formation of brain abscesses. Clinical manifestations include headaches, nausea, vomiting, declining mental status, signs of increased ICP, and new focal neurologic findings in patients who had been improving after trauma. Evaluation and treatment of brain abscess are discussed in Chapter 99.

**Cranial Osteomyelitis.** Cranial osteomyelitis can occur after penetrating injury to the skull. The clinical manifestations include pain, tenderness, swelling, and warmth at the infected site. More than 50% of cases are obvious on plain skull radiographs. Technetium bone scans can help in the diagnosis when the skull radiographs are negative, but false-positive bone scans occur in patients with previous trauma or craniotomy. Adding a gallium scan helps differentiate infection from other causes of a positive technetium scan. Patients with posttraumatic cranial osteomyelitis require surgical debridement and removal of the infected bone. Antibiotic choice is determined by culture results. If systemic symptoms are present, an underlying subdural or epidural empyema is often present.

**Medical Complications**

There are several systemic manifestations of TBI that can occur in the absence of any specific organ injury or systemic infection. The nature and severity of these manifestations depend mainly on the severity of the brain injury.

**Disseminated Intravascular Coagulation.** The injured brain is a source of tissue thromboplastin that activates the extrinsic clotting system. Disseminated intravascular coagulation (DIC) can develop within hours after any injury disrupting brain tissue. Cerebral intravascular coagulation is a universal response to TBI and is found in tissues from surgical specimens of human cerebral contusions. Coagulation abnormalities, including systemic DIC, are detected in over 50% of severe TBI patients.\textsuperscript{109} Isolated severe TBI patients who develop coagulopathy have higher mortality rates than isolated severe TBI patients without coagulopathy.\textsuperscript{110} DIC not only increases morbidity and mortality after severe TBI, it increases the risk of delayed intracranial hemorrhage. If a stable
patient with DIC suddenly deteriorates, a repeat CT scan should be obtained to rule out hemorrhage.

The extent of tissue destruction determines the degree of DIC that develops. The diagnosis is based on abnormalities in the international normalized ratio (INR), prothrombin time (PT), partial thromboplastin time (PTT), platelets, plasma fibrinogen levels, and fibrin degradation products. Patients with coagulopathy or abnormal platelet function require interventions to correct these. Furthermore, patients with moderate or severe head trauma are at extremely high risk to experience venous thromboembolic events (VTEs) after admission to the hospital. Recent evidence has suggested that patients with moderate or severe head trauma can be safely treated with low-molecular-weight heparin to reduce the risk of VTEs without significantly increasing the risk of intracerebral hematoma expansion.

Neurogenic Pulmonary Edema. Neurogenic pulmonary edema can develop minutes to days after head trauma. It leads to an increase in extravascular fluids in the lungs, which causes hypoxia and decreased lung compliance. Theories on its pathophysiology include the following: (1) catecholamine surge or blast from the TBI, resulting in increased intravascular pressure, increased capillary permeability, and hydrostatic edema; and (2) a systemic inflammatory reaction leading to endothelial damage and vasogenic edema. Treatment of acute lung injury in TBI is challenging because measures such as hyperventilation, fluid restriction, and prone ventilation (which raises ICP) that are routinely used to treat lung injury are contraindicated in TBI. Positive end-expiratory pressure (PEEP) is commonly used to reduce lung fluids. Although PEEP is thought to increase ICP by reducing venous return, studies have shown that with adequate intravascular volume and MAE, PEEP does not adversely affect ICP and may reduce ICP by improving cerebral oxygenation. Furthermore, controlling ICP also appears to reduce the neurogenic stimulation that may contribute to this edema. Close ICP and ventilator management are essential to improved outcomes in patients with acute lung injury secondary to TBI.

Cardiac Dysfunction. A variety of cardiac rhythm, rate, and conduction abnormalities are detected after TBI. Harvey Cushing noted a connection between cardiac dysrhythmias and intracranial bleeding in the early 20th century. Many brain-injured patients with cardiac dysfunction have concurrent myocardial injury from underlying disease or chest injury. However, brain injury can cause primary cardiac dysfunction. High levels of circulating catecholamines have been measured in head-injured patients, with increased sympathetic nervous system activation. Cardiac rhythm abnormalities have been reported in up to 70% of all patients with tSAH and more than 50% of all patients with traumatic intracranial hemorrhage. In SAH, the cardiac dysrhythmias may result from autonomic nervous system dysfunction that subsequently affects ventricular polarization.

The most common cardiac dysrhythmia after TBI is supraventricular tachycardia, but many other rhythms have been observed. Findings on the electrocardiogram include diffuse large upright or inverted T waves, prolonged QT intervals, ST segment depression or elevation, and U waves. The primary goal in the emergency management of cardiac dysfunction after head trauma is ensuring adequate tissue perfusion and avoiding hypoxia. Dysrhythmias in head-injured patients often resolve as ICP is reduced.

Disposition

All patients with moderate TBI should be admitted for a period of observation, even with an initial, apparently normal CT scan. Frequent neurologic checks should be initiated, and a repeat CT scan is indicated if the patient’s condition deteriorates or fails to improve over the first 48 hours after trauma. In patients with persistent symptoms of headache, confusion, or memory difficulties, delayed MRI may define lesions in the regions related to cognition that cannot be seen on CT. Although not useful in the acute setting, MRI has prognostic value during subsequent care and assists in directing the future rehabilitation of these patients.

All patients with moderate to severe head trauma require imaging to determine the extent and nature of the brain injury and necessity of neurosurgical intervention. Neurosurgical consultation should be obtained as soon as possible to help direct the patient’s subsequent management. Moderate and severely head-injured patients require admission to an institution capable of intensive neurosurgical care and acute neurosurgical intervention. If this is not available at the receiving hospital, the patient should be transferred to an appropriate institution.

MILD TRAUMATIC BRAIN INJURY

Clinical Features and History

As with moderate and severe TB, a comprehensive history includes information from the patient, prehospital personnel, family members and witnesses about the mechanism of injury, events before and after the injury, age, comorbidities, coagulopathies (eg, hemophilia, Von Willebrand disease, hepatic insufficiency, use of anticoagulants), consumption of alcohol or drugs, changes in mental status or deteriorating GCS scores, previous TBI or concussion, symptoms of other potential injuries, and TBI symptoms (including postconcussive symptoms). By definition, the diagnosis of MTBI is largely clinical. It is not uncommon for MTBI symptoms to dissipate by the time patients reach the ED. It is important to ask patients specifically about symptoms of disorientation, confusion, amnesia, or disordered awareness, with or without loss of consciousness. A number of MTBI patients do not experience a loss of consciousness and, if they do, it is difficult to quantify unless there are witnesses. Patients may report headache, dizziness (vertigo or imbalance), lack of awareness of surroundings, and nausea and vomiting. Patients may also complain of mood and cognitive disturbances, sensitivity to light and noise, impaired verbal memory, delayed language comprehension, and slowed speech and exhibit balance problems.

Alert patients are questioned regarding cervical spine pain. Immobilization is indicated until cervical spine injury is excluded.

Physical Examination

The general physical examination is as for the patient with moderate or severe head injury, as described earlier. A more detailed neurologic examination is often possible in patients with mild MTBI who are able to interact with the examiner and cooperate with the examination. The examination includes evaluation of the cranial nerves, because CN injuries can occur in MTBI, particularly in conjunction with skull base fractures. Assess for anoma and hyposmia, because the olfactory nerve (CN I) is one of the most common CNs affected after MTBI. This may be done by having the patient smell ground coffee or a citrus-scented beverage or cleaning agent. The facial nerve (CN VII) and oculomotor nerves (CNs III, IV, and VI) are also frequently injured, so assess for facial paralysis, change in taste, and/or diplopia. In MTBI, CNs IV and VI are more commonly injured than CN III. CN VII palsy may indicate a fracture of the temporal bone, particularly if it occurs in association with decreased hearing (CN VIII). Hearing impairment can be one of the more subtle deficits seen after TBI. Facial pain (CN V) and occipital neuralgia may also occur in association with MTBI. Assess coordination, balance, and gait. MTBI patients often can have difficulty with the finger-nose-finger test and will use slow purposeful movements to complete the task.
Romberg testing may demonstrate significant sway. Vestibular problems can affect balance and gait. Assess sensation, motor strength, symmetry, and reflexes. Note if the patient displays a peculiar flat affect, appears devoid of emotion, and speaks in a slow monotone voice without inflection, which may indicate damage to the prefrontal cortex or frontal lobes.

### Differential Diagnosis

MTBI (GCS score of 13–15) is characterized by symptoms of confusion and amnesia, with or without preceding loss of consciousness. The differential diagnosis, in the context of trauma, therefore includes intoxication (drugs, alcohol, medications), posttraumatic seizures and postictal state, hypoglycemia, and other injuries that may impair a patient’s ability to communicate, such as hypoxemia or hypoperfusion (from extracranial injuries), facial bone fractures, cervical spine or spinal cord injuries, injuries to the eyes or tympanic membranes, laryngeal or vocal cord injuries, and vascular injuries of the neck. Patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be a MTBI, even if the patient presents with a GCS score of 15. In such a case, the injury would be reclassified as moderate or severe TBI.

Prior to the trauma, patients may have experienced a syncope, episode, seizure, or cardiac event that produced a loss of consciousness that led to the subsequent trauma. For example, an MVC may have resulted from the driver becoming distracted or incapacitated by important symptoms suggestive of an unrelated disorder. Therefore, potential precipitants to the trauma should also be considered in the differential diagnosis.

An MTBI or concussion may go unrecognized in the ED, especially if symptoms are transient or if more visible injuries dominate the assessment. An underlying dementia or psychiatric illness may make it very difficult to distinguish an MTBI from baseline cognitive or mental dysfunction. Other conditions that could confound the diagnosis include stroke, encephalopathies (eg, hepatic, uremic), delirium from alcohol or drug withdrawal, neurologic conditions (eg, Parkinson’s or Alzheimer’s disease, autism), and infection or sepsis. Even low-mechanism trauma should alert the emergency clinician to the possibility of brain injury in susceptible populations. A thorough medical evaluation is critical.

### Diagnostic Testing

#### Neuroimaging in the Emergency Department With Computed Tomography

CT imaging of the head is the diagnostic standard for identifying intracranial injury in the ED. However, CT is associated with exposure to ionizing radiation and higher health care costs. Therefore, a number of clinical decision rules have been prospectively derived and validated to identify patients at risk for neurosurgical intervention and intracranial lesions on CT scan in adult patients with suspected MTBI in the ED. These include the New Orleans Criteria (NOC), Canadian Computed Tomography Head Rule (CCHR), and National Emergency X–Radiography Utilization Study II (NEXUS-II; Box 34.4). Others have developed guidelines based on available evidence, including the American College of Emergency Physicians clinical policy on neuroimaging of adult ED patients with MTBI (ACEP), National Institute for Health and Clinical Excellence (NICE), Neurotraumatology Committee of the World Federation of Neurosurgical Societies (WFNS), Scandinavian Neurotrauma Committee, and Scottish Intercollegiate Guidelines Network (SIGN). Although most of the rules and guidelines produce high sensitivities for detecting neurosurgical intervention and intracranial lesions, the specificities are variable. Additional clinical decision rules have been developed for use in the pediatric population (see Chapter 165).

The most widely researched clinical decision rules for MTBI are the CCHR and NOC, with external validation studies in the United States and internationally. The CCHR was developed for use in patients with a GCS score of 13 to 15; it divides clinical variables into high- and medium-risk categories. The NOC was developed for use in patients with a GCS score of 15 only and is composed of seven clinical variables. For injuries requiring neurosurgical intervention, both the CCHR and NOC have a high sensitivity (99%–100%) but the CCHR has a much higher specificity (CCHR, 48%–77%; NOC, 3%–31%). For identification of traumatic intracranial lesions on CT, the CCHR and NOC have a high sensitivity (CCHR, 80%–100%; NOC, 95%–100%) but specificity is higher with the CCHR. In terms of potential for CT reduction, adherence to the NOC results in an increase in head CT use; adherence to the CCHR results in a decrease in head CT use compared to current practice. Imaging of patients in this population should follow a validated guideline. Clinicians in emergency medicine, trauma surgery, neurosurgery and, as indicated, neurology, should review the relevant guidelines (CCHR, NOC) and select the system thought to be most applicable for their setting and patient population. Oversight should ensure that cases not following the adopted guidelines are reviewed and feedback is provided to emergency clinicians.

CSF, Cerebrospinal fluid; GCS, Glasgow Coma Scale.
Other Neuroimaging Modalities

Structural MRI. CT is the imaging modality of choice for initial screening to exclude serious traumatic intracranial lesions in MTBI. However, many patients who develop persistent symptoms and cognitive deficits have no detectable abnormalities on CT. MRI is better than CT in detecting posttraumatic ischemic infarctions, subacute nonhemorrhagic lesions and contusions, axonal shear injury, and lesions in the brainstem or posterior fossa. Structural MRI, particularly at a 3-T strength, improves structural sensitivity, can be performed when neurologic findings cannot be explained by CT, and is particularly valuable in assessing the brainstem, posterior fossa, and brain parenchyma adjacent to the calvaria. Structural MRI (without contrast) can also be used for the evaluation of TBI-related symptoms in the subacute and chronic phases of injury.

Susceptibility-Weighted Imaging. A significant advancement in the imaging of MTBI has been the development of susceptibility-weighted imaging (SWI). This technique is an imaging method that grew out of and is part of MRI. It uses differences in magnetic susceptibility between tissues and is particularly helpful for the evaluation of TAI and punctate hemorrhages in the deep subcortical white matter not visible on CT or structural MRI scans. It takes about 4 minutes to image the entire brain and, in the ED, SWI detects additional lesions 30% of the time compared to CT and structural MRI. The number and volume of SWI hemorrhagic lesions correlate with clinical outcome.

Diffusion Tensor Imaging. DTI uses MRI technology to analyze the movement of water molecules in the white matter of the brain and also provides the opportunity to perform tractography—visualization of major white matter pathways—to assess damaged nerve fiber tracts. DTI detects white matter abnormalities and underlying cognitive deficits when conventional imaging is normal and may be a sensitive marker of TAI in MTBI at acute and chronic stages of its clinical course.

Computed Tomography Angiography and Magnetic Resonance Angiography. Vascular imaging such as CT angiography and MR angiography are not recommended routinely for patients with MTBI unless there is suspicion of a traumatic vascular injury, such as pseudoaneurysm, dissection, or uncontrolled hemorrhage. Typically vascular injuries occur with penetrating trauma, skull base fractures, blunt neck trauma, and/or skull base or cervical spine fractures. Independent predictors of arterial injury in blunt trauma include cervical facet subluxation or dislocation, fracture lines approaching an artery, and high-impact injury mechanisms.

Ancillary Studies

Laboratory Testing. Laboratory tests are not needed for patients with isolated MTBI except for a bedside glucose level in those with a GCS score less than 15. Coagulation parameters such as INR, PT, and PTT are indicated for those with coagulopathies or suspected liver disease and those on anticoagulants. Although not in clinical use at this time, glial fibrillary acidic protein (GFAP) is a promising brain-specific biomarker for MTBI in adults and children (Fig. 34.16). GFAP is released into serum following a MTBI within 1 hour of injury, and its level is elevated in MTBI patients with axonal injury, as evidenced by MRI at 3 months postinjury. It can remain elevated for seven days post-injury. In adults and children, studies have shown that serum GFAP levels distinguish MTBI patients from trauma patients without TBI and detect intracranial lesions on CT with a sensitivity of 94% to 100%.

Fig. 34.16. Neuron and neuroanatomic locations of potential TBI biomarkers. S100β is the major low-affinity calcium binding protein in astrocytes that helps regulate intracellular levels of calcium. Glial fibrillary acidic protein (GFAP) is a monomeric intermediate protein found in the astroglial skeleton and in white and gray brain matter and is strongly upregulated during astrogliosis. Neuron-specific enolase (NSE) is one of the five isozymes of the glycolytic enzyme enolase found in central and peripheral neuronal cell bodies. UCH-L1 is highly abundant in neurons and was previously used as a histologic marker for neurons. Alpha II-spectrin is the major structural component of the cortical membrane cytoskeleton and is particularly abundant in axons and presynaptic terminals. Tau is an intracellular, microtubule-associated protein that is highly enriched in axons. Neurofilaments are heteropolymeric components of the neuron cytoskeleton. (From Papa L: Exploring serum biomarkers for mild traumatic brain injury. In Kobeissy F, editor: Brain neurotrauma: molecular, neuropsychological, and rehabilitation aspects in brain injury models. London, 2015, CRC Press, p 303.)
Neuropsychological Testing. Neuropsychological testing is used to assess cognitive function after MTBI and is commonly used following sports concussion. Although not routinely done in the ED, referral to a neuropsychologist is warranted for patients having persistent symptoms following a concussion.

Disposition
Most patients with MTBI can be discharged from the ED with a normal examination and after a reasonable period of ED observation (4–6 hours) or following a negative head CT scan, except in the presence of therapeutic anticoagulation, when more prolonged observation, up to 12 hours, sometimes with repeat head CT, is warranted.\(^1\) If the emergency clinician decides that the patient with MTBI can be sent home, an appropriate early follow-up should be arranged. Providing patients and families with educational information about postconcussive syndrome and what to expect after injury helps improve outcome. Patients should also be given contact information for the brain injury association in their state. State brain injury associations can connect patients and families with support groups, programs, and professionals who understand the injury (www.biausa.org/mild-brain-injury.htm).

Patients should be discharged with instructions describing the signs and symptoms of acute and delayed complications of MTBI, have access to a telephone, and be monitored in the acute post-trauma period by a responsible sober adult. All discharge instructions should be written and told to a responsible third party. Warning signs for acute deterioration, such as inability to waken the patient, severe or worsening headaches, somnolence or confusion, restlessness, unsteadiness, or seizures, difficulties with vision, vomiting, fever, or stiff neck, urinary or bowel incontinence, and weakness or numbness involving any part of the body should prompt the caregiver to seek immediate medical help. If any doubt exists regarding the safety of the discharged patient with MTBI, a brief inpatient observation period (12–24 hours) is advisable.

If resources allow, prolonged ED observation may be practical in some circumstances. For example, intoxicated patients with MTBI who otherwise fulfill low-risk criteria should undergo serial evaluations in the ED until clinical sobriety is achieved. In these patients, a CT scan may be unnecessary, and ED observation is beneficial.

If a patient with MTBI returns to the ED because of persistent symptoms, delayed complications of injury should be sought. If a CT scan was not initially obtained, the intensity of symptoms may guide the decision to obtain a CT scan at the second visit. If a negative scan was initially obtained, the likelihood of the subsequent development of an intracranial lesion is exceedingly low.\(^7,8\)

The decision to rescanning more complex in patients from certain subgroups who may be considered more likely to develop delayed complications. These include patients on anticoagulation, those with preexisting neurologic injuries that may obscure an examination, and those with previous neurosurgical procedures (eg, ventriculoperitoneal shunts). The literature about repeat CT scanning in MTBI suggests that patients who are unchanged or improving neurologically do not benefit from a repeat CT, but repeat imaging is indicated to assess a deteriorating patient.\(^7,8\)

Complications
In addition to being at risk for serious intracranial injuries, patients with a suspected MTBI can have elusive axonal injuries\(^15,142\) and, over the long term, can suffer impairment of physical, cognitive, and psychosocial functioning.\(^143\) It has been reported that more than one-third of MTBI patients do not resume work until 1 to 3 months after their injury, and lingering cognitive complaints are reported by as many as 15% of patients 1 year postinjury.\(^144\) Recovery can also be complicated by psychiatric or substance abuse problems, health problems, concurrent orthopedic and/or traumatic injuries, chronic pain, lack of family and social support, unemployment, and litigation.\(^145\)

Postconcussive Syndrome
Postconcussive syndrome (PCS) refers to a constellation of symptoms that include somatic (headache, dizziness, vertigo, nausea, fatigue, sensitivity to noise and light), cognitive (difficulties with attention, concentration, and memory) and affective complaints (irritability, anxiety, depression, emotional lability) that occur following a MTBI or concussion and persist beyond the expected recovery period. Affected patients commonly report headache, dizziness, memory or concentration difficulties, irritability, sleep disturbances, dizziness, and depression. There appears to be psychological and structural components to postconcussive syndrome, because patients with a history of migraines, depression, or anxiety are more likely to experience postconcussive syndrome.\(^146\) The severity and duration of postconcussive symptoms may correlate with the abnormalitities found with early functional imaging.\(^147\) Studies of ED patients have indicated that as many as 30% of patients with a discharge diagnosis of MTBI will have symptoms at 3 months postinjury, and up to 15% will continue to be symptomatic at 1 year postinjury. In the ED, patients with more severe symptoms, such as prolonged amnesia, dizziness, headache, anxiety, noise sensitivity, or trouble with verbal recall have been shown to be at a higher risk of developing postconcussive syndrome.\(^148\) Other factors that have been identified as conferring an increased risk for the development of PCS symptoms include prior MTBI, history of depression and/or anxiety, multiple injuries, forgetfulness or poor memory, noise and/or light sensitivity, and history of migraine.\(^149,150\) There are a wide range of treatments being studied, including cognitive and behavioral therapies, medications, devices, dietary supplements, return to activity and rest and others.\(^151\)

Seizures
Posttraumatic seizures occur in fewer than 1% of MTBI patients, and acute antiseizure prophylaxis is not indicated.\(^152,153\) The cumulative incidence of posttraumatic epilepsy in the first 3 to 5 years after discharge is about 4% for patients with MTBI.\(^153\) PTE usually develops within the first 2 years after injury. Prophylactic treatment with anticonvulsants does not prevent delayed-onset PTE and is not recommended.\(^154\)

Posttraumatic Transient Cortical Blindness
Posttraumatic transient cortical blindness syndrome is characterized by transient visual loss, normal pupillary response, and normal funduscopic examination within hours following MTBI. This syndrome has been reported mainly in children. In most cases, vision returns to normal within minutes to hours (usually within 24 hours) following injury and leaves no neurologic sequelae. Headache, confusion, irritability, anxiety, nausea, and vomiting are common related symptoms. Although the mechanism for the transient blindness is unknown, it has been suggested that it is an abnormal vascular response to trauma, with resultant transient hypoxia and cerebral dysfunction.

Special Populations With Mild Traumatic Brain Injury

Mild Traumatic Brain Injury and Concussion in Sports
It has been estimated that 3.8 million concussions occur in the United States annually from organized and recreational sports.\(^155\) Football, ice hockey, soccer, and lacrosse tend to have the highest...
concussion incidence rates when calculated by athlete exposure.\textsuperscript{186} Although concussion is under the umbrella of MTBI, the term concussion is typically used to describe MTBI in athletes. It has been suggested that sports-related concussions are associated with less disability and more rapid recovery than concussions in non-athletes. However, neuroimaging has suggested similar patterns of neuronal disruption for sports- and non-sports-related MTBI.\textsuperscript{186} Athletes are more vulnerable to the deleterious long-term effects of MTBI because they are often subjected to repetitive trauma and greater levels of physical exertion during recovery.\textsuperscript{186} Only recently has chronic traumatic encephalopathy (CTE) come to public attention due to autopsy findings in high-profile athletes.\textsuperscript{192} Originally identified in boxers,\textsuperscript{21} CTE has recently been found to occur after other organized sports, including US football, hockey, soccer, and professional wrestling.\textsuperscript{20,22,23} Meta-analyses of neuropsychological outcomes following MTBI have suggested that recovery from impairments in the general population takes longer (weeks to months) than in athletes who tend to show recovery within 2 to 14 days following concussion. Among athletes there is a tremendous motivation to return to play. As a result, athletes often underreport symptoms, return to their regular activities prematurely, and may create the impression that they recover more quickly than they actually do.\textsuperscript{186}

Second-impact syndrome is thought to be an exceedingly rare yet catastrophic, and sometimes fatal, consequence of repeated MTBI in sports occurring within a short period of time (days). It is defined as occurring when “an athlete who has sustained an initial head trauma, most often a concussion, sustains a second head trauma before symptoms associated with the first have fully cleared,”\textsuperscript{193,194} leading to diffuse cerebral swelling. The controversy surrounding second-impact syndrome is whether a repeated head trauma is required to cause it or whether the brain swelling is the result of a single blow to the head.\textsuperscript{195} Most reported cases of this entity, including the index case, actually sustained a single blow and did not involve a “second” impact. Furthermore, many reported cases had evidence of other structural brain injuries, such as acute subdural hematomas, in addition to the cerebral swelling. Based on the published case studies, the two groups of athletes at a higher risk of this entity are boxers and children and adolescents. Accordingly, the Centers for Disease Control and Prevention (CDC) has developed the HEADS UP Concussion in Youth Sports initiative to offer information about preventing, recognizing, and responding to a concussion to coaches, parents, and athletes involved in youth sports.

In 2013, several new or updated clinical practice guidelines and position statements were published on the diagnosis, treatment, and management of MTBI and concussion in sports. Three of these guidelines were produced by the American Medical Society for Sports Medicine,\textsuperscript{186} American Academy of Neurology,\textsuperscript{186} and Zurich Consensus working group.\textsuperscript{186} It was agreed that concussion is a clinical diagnosis that is ideally made by a licensed health care provider with experience in the evaluation and management of patients with a concussion. Any athlete suspected of having a concussion should be immediately removed from play. Graded symptom and clinical sign checklists can be useful, particularly if they can be compared to preseason data.\textsuperscript{186} The Sport Concussion Assessment Tool, third edition (SCAT3), is a standardized tool for evaluating injured athletes for concussion and can be used in athletes 13 years of age and older. It replaces the original SCAT and SCAT2, published in 2005 and 2009, respectively.\textsuperscript{192} (http://bjsm.bmj.com/content/47/5/259.full.pdf). The SCAT3 takes 15 to 20 minutes to complete and computes a composite score comprised of the GCS, Standardized Assessment of Concussion (SAC) score (cognitive and physical evaluation, delayed recall), and balance assessment score (modified Balanced Error Scoring System [BESS]). For children from 5 to 12 years of age, the Child-SCAT3 is used (http://bjsm.bmj.com/content/47/5/263.full.pdf). The SCAT3 also includes a page of information to be given to the athlete and parents after discharge.

When evaluating an athlete with suspected MTBI or concussion in the ED, obtain a comprehensive history, taking into account additional information from parents, coaches, teammates, and eyewitnesses, such as mechanism of injury, events after the injury, changes in mental status or deteriorating GCS scores, prior MTBI or concussion, current symptoms (including postconcussive symptoms), and symptoms of other potential injuries (e.g., cervical spine injury). As with any trauma patient, perform a thorough examination looking for other signs of trauma, and remember to evaluate for cervical spine injury. The neurologic examination should include an assessment of pupillary reactivity, cognitive functioning, and gait and balance. As with all MTBI patients, monitoring of the injured athlete with serial assessments is critical, because signs and symptoms may evolve over hours after injury. A head CT scans is not routinely recommended but should be considered if there is clinical suspicion of a traumatic intracranial lesion. Before return to play, a gradual, a stepwise increase in general physical activity, followed by sports-specific activities, is recommended. Progression to more strenuous steps is only recommended if the athlete is asymptomatic at the current level of activity (Table 34.3). Ideally, a multidisciplinary approach to assessment and management is used, with the inclusion of sports medicine specialists from various subspecialties, as

appropriate for the athlete’s symptoms and signs. Because many states have passed laws regarding concussion management in organized youth sports, it is good practice for emergency clinicians to familiarize themselves with the laws of the state in which they are practicing.

Key recommendations of all three recent position statements have stated that any athlete suspected of having a concussion should not be allowed to return to play on the day of the injury. Investigators have found that this can be delayed beyond the first 24 hours in 1% to 3% of cases.

The most recent guidelines advocate observation for the first 24 hours following MTBI. There should be a low threshold for factor replacement for the patient. Patients who sustain head trauma and are on anticoagulation medications should undergo a CT scan without contrast and should be considered for anticoagulated patients with a high risk for delayed bleeding (e.g., supratherapeutic INR), those with significant comorbidities, those who live alone, and those who cannot return to the hospital in a timely manner should symptoms of delayed bleeding appear. This underscores the importance of detailed patient instructions on discharge from the hospital.

Patients with therapeutic anticoagulation and a negative initial head CT scan do not need to have their anticoagulation reversed. Patients on warfarin with traumatic intracranial lesions should undergo reversal with fresh-frozen plasma or prothrombin complex concentrates, and vitamin K should also be initiated in the ED. However, the transfusion of platelets in patients on antplatelet medications does not reduce mortality. Dabigatran can be reversed with hemodialysis, but rivaroxaban and apixaban cannot. Idarucizumab, a Fab fragment of a monoclonal antibody directed specifically against dabigatran, was approved by the US Food And Drug Administration in 2015 for emergency surgery and urgent procedures and for life-threatening or uncontrolled bleeding. The recommended dose for idarucizumab is 5 g (2.5 g/vial), administered as two consecutive 2.5-g IV infusions or bolus injection by injecting both vials consecutively, one after another, via syringe. Andexanet alfa is a class-specific antidote targeted to reverse the oral direct factor Xa inhibitors as well as the indirect factor IIa or Xa inhibitors, as well as the indirect inhibitor, enoxaparin; ciraparantag is a universal antidote targeted to reverse the direct thrombin and factor Xa inhibitors, as well as the indirect inhibitor, enoxaparin. Studies evaluating these antidotes in the setting of TBI are currently lacking.

**Military Personnel and Blast Injury**

Mild TBI is also a common injury among soldiers who have participated in combat. Explosive blast brain injury is becoming recognized as a distinct entity from the penetrating form of blast injury and closed brain injury. In recent US conflicts in Iraq and Afghanistan, over 60% of combat casualties were from explosive blast, mostly from improvised explosive devices (IEDs). Other mechanisms included falls, motor vehicle accidents, fragment shrapnel, and bullet wounds. In an explosive blast, the primary injury to the brain occurs when the physical forces emanating from a detonation impact loading on the head and consequently the brain. The definition of MTBI from the American Congress of Rehabilitation Medicine is currently being applied to explosive blast TBI (including loss of consciousness, amnesia, altered mental status, and focal neurologic deficit). A soldier who has been exposed to a blast may lack overt evidence of a head injury, such as lacerations, bruising, or hematoma. Recognizing an MTBI acutely is important so that the soldier can receive appropriate medical attention and be removed from combat-related duty to avoid another TBI. After the first blast exposure, many soldiers do not recognize that they may have been injured, and thus will not seek medical care. The first indication of injury may be persistent postconcussive symptoms, such as headaches, vertigo, short-term memory loss, and difficulty concentrating and multitasking. The clinical presentation of explosive blast MTBI can be confused by the considerable overlap between the symptoms of MTBI and posttraumatic stress disorder (PTSD), such as mood fluctuations, sleep disturbances, and difficulty concentrating. Both may occur in the same individual. PTSD symptoms usually include bursts of anger, irritability, hypervigilance, and increased startle response.

**Anticoagulated Patients**

**Patients on Anticoagulant Medications.** Most clinical decision making rules exclude patients who are taking anticoagulants such as warfarin (vitamin K antagonists), antiplatelet medications (aspirin, clopidogrel), and non–vitamin K antagonists (factor IIa or Xa inhibitors). Overall, there is a higher incidence of intracranial bleeding in TBI patients on anticoagulants following head trauma, with an incidence of up to 22% in patients with MTBI. As a result, most practice guidelines propose that patients who sustain head trauma and are on anticoagulation treatment should undergo a CT scan without contrast and should have the INR determined, because an initial INR greater than 3 confers a much higher risk of intracranial bleeding. Some guidelines advocate observation for the first 24 hours following MTBI, along with a second CT scan. However, intracranial bleeding can be delayed beyond the first 24 hours in 1% to 3% of anticoagulated patients and can present as late as 4 weeks following injury. Antiplatelet medications are more likely to lead to immediate traumatic intracranial hemorrhage (12%) compared with patients receiving warfarin (5%), who are more likely to have delayed bleeding. In anticoagulated patients with a negative CT scan, routine admission is not required. Admission should be considered for anticoagulated patients with a high risk for delayed bleeding (e.g., supratherapeutic INR), those with significant comorbidities, those who live alone, and those who cannot return to the hospital in a timely manner should symptoms of delayed bleeding appear. This underscores the importance of detailed patient instructions on discharge from the hospital.

**Patients With Inherent Bleeding Disorders.** The most serious site of bleeding for children and adults with inherent bleeding disorders, such as hemophilia, is the CNS. Intracranial hemorrhage in patients with hemophilia can occur spontaneously or following mild head trauma. Over 50% of hemophiliacs with MTBI who have intracranial bleeding are initially asymptomatic, with a normal neurologic examination. Therefore, patients with inherent bleeding disorders should undergo head CT following a MTBI. There should be a low threshold for factor replacement (e.g., factor VIII or IX, cryoprecipitate, fresh-frozen plasma) in patients with severe hemophilia or in those with MTBI symptoms, even prior to performing head CT.

**Head Trauma in Older Adults**

Older patients have increased morbidity and mortality from TBI and have higher rates of intracranial injuries following head trauma. They also experience MTBI more frequently than severe TBI. Furthermore, frequent falls put them at risk for repetitive brain injury. Within 7 months following a mild or moderate TBI, older patients can show a decline in language, memory, executive function, activities of daily living, and mood compared with their preinjury functioning and compared to controls. Accordingly, older adults with preinjury warfarin or clopidogrel use are at an increased risk for unfavorable long-term neurologic outcomes compared with similar patients without preinjury use of these medications.

With age, the brain atrophies and creates more space within the cranial vault for blood to accumulate before symptoms appear. Moreover, with atrophy, comes stretching of bridging veins that may tear and lead to subdural hematomas more easily. Therefore, older adults can have significant hemorrhage into their brain and not show signs of deterioration, especially if their baseline cognitive functioning is impaired. Occult intracranial hemorrhages occur in over 2% of older patients with head trauma.
Alcohol abuse is one of the most prevalent comorbid conditions found in older patients admitted to the hospital with TBI, so screening for alcohol abuse in older patients with head trauma is recommended. Elder abuse is an important consideration in this population as well and should be assessed during the ED evaluation.

The presence of comorbid medical conditions, use of anticoagulants, preexisting cognitive deficits, polypharmacy, alcohol consumption, and unique physiology of the aging brain make it challenging for the emergency clinician to detect brain injury. Even low-mechanism falls should prompt health care providers to consider the possibility of brain injury in older patients. Many clinical decision rules recommend CT for patients older than 60 to 65 years following any suspected MTBI. Reducing the risk of falls in older adults can reduce the risk of TBI. Particular attention needs to be given to polypharmacy, drug interactions, safety issues in the living environment, risk of elder abuse, and covert alcohol consumption.

**KEY CONCEPTS**

- **Head trauma** is a broad term describing an external trauma to the craniofacial area of the body from blunt, penetrating, blast, rotational, or acceleration-deceleration forces, the term **brain injury** refers to a clinically evident injury on physical examination, and the term **TBI** is often categorized into mild (GCS score, 13–15), moderate (GCS score, 9–12), and severe (GCS score, 3–8), but this actually represents a spectrum of injury. Patients with a presentation GCS score of 13 to 15 who are stable or improving are exceedingly unlikely to have CT findings that warrant intervention.

**Severe and Moderate Traumatic Brain Injuries**

- Secondary systemic insults such as hypoxia and hypotension worsen neurologic outcome and should be corrected as soon as detected.
- Noncontrast head CT is the imaging modality of first choice when TBI is suspected.
- The motor component of the GCS is the strongest predictor of outcome following TBI.

**Penetrating Head Trauma**

- Anticonvulvent prophylaxis with phenytoin and broad-spectrum antibiotics should be given to patients with penetrating brain injuries for 7 days postinjury.

**Mild Traumatic Brain Injury**

- Patients can deteriorate from an expanding intracranial hematoma after what appears clinically to be MTBI, and should undergo serial evaluations, including serial GCS scoring.
- An MTBI can be easily overlooked when an alert patient presents with other more obvious traumatic injuries. Specifically, ask patients about symptoms of disorientation, confusion, amnesia, or disordered awareness (with or without loss of consciousness).
- Imaging of patients in this population should follow a validated guideline, such as the Canadian CT Head Rule and New Orleans Criteria. Emergency clinicians should work collaboratively to select the system thought to be most applicable for their setting and patient population.
- Alcohol and drug use affects the GCS score and significantly obscures the neurologic examination. Intoxicated individuals are high-risk patients.
- Most patients with MTBI can be discharged from the ED with a normal examination and after a reasonable period of ED observation (4–6 hours) following a negative head CT.
- Patients should be discharged with instructions describing the signs and symptoms of acute and delayed complications of MTBI. All discharge instructions should be written and relayed to a responsible third party.

**Special Populations**

- Any athlete suspected of having a concussion should be immediately removed from play.
- Athletes with concussion should not return to play until they have been evaluated by a licensed health care provider with expertise in concussion management. There should be a gradual stepwise increase in physical activity.
- Older adults can have significant hemorrhage into their brain and not show signs of deterioration, especially if their baseline cognitive functioning is impaired. Patients older than 60 years should have a CT scan obtained.
- Falls in older adults, including low-mechanism falls, should prompt health care providers to consider the possibility of brain injury.

Chapter 34: Questions & Answers

34.1. Injured brain ischemia may be seen with partial pressure of carbon dioxide \( (P_{CO_2}) \) levels below what value?

A. 35 mm Hg
B. 30 mm Hg
C. 25 mm Hg
D. 20 mm Hg

Answer: D. Cerebral vasculature is exquisitely sensitive to \( P_{CO_2} \) levels. The degree of vasoconstriction below a \( P_{CO_2} \) of 20 mm Hg may be so severe as to induce ischemia. Modest hyperventilation to a target of 30 to 35 mm Hg is recommended once acute resuscitation is completed.

34.2. Which of the following statements is true regarding cerebral blood flow (CBF), cerebral perfusion pressure (CPP), and intracranial pressure (ICP)?

A. CBF autoregulation is lost below a CPP of 60 mm Hg.
B. CPP closely parallels diastolic blood pressure.
C. Normal ICP is 65 to 195 mm Hg.
D. CPP = mean arterial pressure (MAP) − ICP.
E. The only resistance to CBF is ICP.

Answer: D. CBF depends on CPP, which is the blood flow pressure gradient. CBF resistance is provided by mean systemic venous pressures and ICP, predominantly by the latter. CPP closely parallels MAP offset by ICP; thus, the formula CPP = MAP − ICP. ICP is estimated clinically by the central venous pressure unless a ventricular catheter is in place and ICP cannot be directly determined. CBF autoregulation is lost below a CPP of 40 mm Hg. Normal ICP is 5 to 15 mm Hg or 65 to 195 mm H₂O.

34.3. Which of the following parameters are associated with a worsened outcome after traumatic brain injury (TBI)?

A. Both D and E
B. Core body temperature > 37.5° C (99.5° F)
C. None of the above
D. Partial pressure of oxygen \( (P_{O_2}) \) < 60 mm Hg
E. Systolic blood pressure < 90 mm Hg

Answer: A. The following are associated with worsened outcomes after TBI:
- Hematocrit (Hct) < 30%
- Temperature > 38.5° C (101.3° F)
- Systemic blood pressure (SBP) < 90 mm Hg
- \( P_{O_2} \) < 60 mm Hg

34.4. A 27-year-old man presents after a motor vehicle collision (MVC) with a severe closed head trauma. On examination, you calculate a Glasgow Coma Scale (GCS) score of 5 and a left dilated pupil, with a sluggish pupillary reflex compared with the right. What other finding will your examination likely reveal?

A. Left carotid bruit
B. Left foot weakness
C. Loss of controlled pain/temperature sensation
D. Right carotid bruit
E. Right-sided hemiparesis

Answer: C. Uncal herniation is the most common posttraumatic herniation syndrome. The initial pressure compresses the third cranial nerve (CN III), causing ipsilateral pupillary sluggishness, ptosis, anisocoria, and impaired extraocular movements. Contralateral hemiparesis can develop early after an initial normal motor examination. In some cases, the contralateral uncus is compressed, resulting in ipsilateral weakness (Kernohan notch syndrome).

34.5. A 24-year-old man presents with a closed head injury after a MVC. The physical examination is remarkable for a sluggish left pupil, right-sided hemiparesis, and a GCS score of 12. What should be the next step in this patient’s management?

A. 3% hypertonic saline IV
B. Intubation and hyperventilation
C. Mannitol, 1 g/kg IV
D. Methylprednisolone IV
E. Pentobarbital IV

Answer: B. The most rapid effect on ICP reduction is achieved via intubation and moderate hyperventilation to a \( P_{CO_2} \) of 30 to 35 mm Hg. The effect peaks within minutes and should be considered a short-term intervention, with an expected ICP reduction of 25%. Prolonged hyperventilation may be dangerous. Steroids may worsen outcome after TBI. Mannitol is generally efficacious and exerts an effect within minutes and lasts hours. Other neuroprotective effects include volume expansion, viscosity reduction, CBF improvement, and free radical scavenging. Hypertonic saline data are encouraging but inconclusive; stronger data exist in the pediatric literature. Barbiturates exert a modest ICP-lowering effect because of their lowering of the cerebral metabolic rate and oxygen demand.

34.6. What is the minimum time after becoming asymptomatic that an individual should refrain from playing sports after a concussion if no loss of consciousness (LOC) or prolonged posttraumatic amnesia occurred at the time of injury?

A. 24 hours
B. 48 hours
C. 1 week
D. 2 weeks
E. 1 month

Answer: C. All current recommendations for return to play after a sports-related concussion state that players with concussion should not return to play for at least 1 week after they have become asymptomatic. This is usually increased to at least a symptom-free month for an extended LOC or prolonged posttraumatic amnesia occurring at the time of the concussion.

34.7. A 15-year-old boy presents after being hit in the head with a baseball. He has a GCS score of 7 and a large hematoma of his scalp, anterior and superior to his right ear. In addition, he is noted to have unequal pupils and a sluggish pupillary light reflex of the right eye. Which of the following is most likely in this patient?

A. Central transtentorial herniation
B. Cerebellotonsillar herniation
C. Downward transtentorial herniation
D. Uncal herniation
E. Upward transtentorial herniation

Answer: D. Uncal herniation is often associated with traumatic extra-axial hematomas in the lateral middle fossa of the temporal lobe. The classic signs and symptoms are caused by compression of the ipsilateral uncus of the temporal lobe on the U-shaped edge of the tentorium cerebelli as the brain is forced through the tentorial hiatus. As compression of the uncus begins, CN III is compressed; anisocoria, ptosis, impaired extraocular movements, and a sluggish pupillary light reflex develop on the side ipsilateral to the expanding mass lesion. This phase may last for minutes to
hours, depending on how rapidly the expanding lesion is changing. As the herniation progresses, compression of the ipsilateral oculomotor nerve eventually causes ipsilateral pupillary dilation and nonreactivity.

Initially, in the uncal herniation process, the motor examination can be normal, but contralateral Babinski responses develop early. Contralateral hemiparesis develops as the ipsilateral peduncle is compressed against the tentorium. With continued progression of the herniation, bilateral decerebrate posturing eventually occurs; decorticate posturing is not always seen with the uncal herniation syndrome. In some patients, the contralateral cerebral peduncle is forced against the opposite edge of the tentorial hiatus. Hemiparesis is then detected ipsilateral to the dilated pupil and mass lesion, termed Kernohan notch syndrome, and causes false-localizing motor findings. As uncal herniation progresses, direct brainstem compression causes additional alterations in the LOC, respiratory pattern, and cardiovascular system. Mental status changes may initially be subtle, such as agitation, restlessness, or confusion, but soon lethargy occurs, with progression to frank coma. The patient’s respiratory pattern may initially be normal, followed by sustained hyperventilation. With continued brainstem compression, an ataxic respiratory pattern develops. The patient’s hemodynamic status may change, with rapid fluctuations in blood pressure and cardiac conduction. Herniation that is uncontrolled progresses rapidly to brainstem failure, cardiovascular collapse, and death.

34.8. Central pontine myelinolysis is a potential adverse event associated with the administration of which of the following medications?
A. Etomidate
B. Hypertonic saline
C. Mannitol
D. Methylprednisolone
E. Pentobarbital

**Answer:** B. Central pontine myelinolysis is a potentially adverse event associated with hypertonic saline administration.

**CHAPTER 35**

**Facial Trauma**

Ryanne J. Mayersak

**PRINCIPLES**

**Background and Importance**

A complex structure vital to the function of the person, the face is comprised of airway openings, entry to the gastrointestinal tract, and special sensory organs, including the eyes, ears, and nose. Facial functioning is essential for eating, speaking, and effective nonverbal communication. The appearance and attractiveness of the face have significant implications for social interactions, sexual attraction, and self-esteem. In one study, patients who had sustained facial trauma experienced long-term sequelae, including unemployment, incarceration, marital difficulties, and negative body image.

Apart from the immediate threat to the patient’s airway and special sense organs, injuries to the face can have serious implications for the patient’s mental health and future functioning. Posttraumatic patients with facial injuries often describe physical, financial, social, and psychological loss. Multiple studies have demonstrated an association between facial trauma and psychological symptoms such as anxiety, depression, and post-traumatic stress disorder. Some institutions are now including screening evaluations regarding supportive interventions, as well as initiating support groups and online resources for facial trauma patients.

Although the emergency clinician’s first goal is to address life-threatening problems successfully, the care of facial injuries is aimed at optimizing the patient’s function and cosmetic appearance. Four main specialties—ophthalmology, plastic surgery, otolaryngology, and oral and maxillofacial surgery—participate in the care of facial injuries. Early consultation with the appropriate specialist can expedite the care of facial injuries.

**Anatomy of the Face**

The face is a complex hollow space encapsulated by a bony structure overlaid with muscle and skin. It includes several special sensory organs—the eyes, ears, nose, and mouth.

**Bones**

The posterior portions of the face form the anterior wall of the calvaria, placing the face and its features in an intimate relationship with the structures of the central nervous system. The anterior facial skeleton is composed of the frontal bone, nasal bones, zygoma, maxillary bones, and mandible (Fig. 35.1). The sphenoid, ethmoid, lacrimal, vomer, and temporal bones lie deep within the facial structure, providing support and important sites for muscular attachments, including the muscles of mastication, speech, and deglutition. This musculature is innervated by cranial nerves IX and X.

**Nerve Supply**

The most anterior muscle layer includes the muscles of facial expression innervated by the seventh cranial nerve (CN), which lies just inferior to the external auditory canal. The trigeminal nerve (CN V) supplies sensation to the face through three major divisions (I–III). The ophthalmic division (CN V1) supplies the upper third of the face, including the eye and nose down to the tip. The maxillary division (CN V2) provides sensory innervation to the midface and includes the infraorbital nerve. The mandibular division (CN V3) supplies sensation to the lower third of the face.

**Ears**

The skeleton of the pinna is cartilage covered in closely apposed skin and rolled into a helical shape with a second ridge, the antihelix, defining the inner concha. The external auditory canal, middle ear, cochlea, semicircular canals, and superior origin of the eustachian tube all lie within the temporal bone.

**Nose**

The nose serves as a major entryway for air and is composed of cartilage and bone covered by skin, with mucosa lining the internal surface. Alar cartilage arches over the entrances to the symmetric, mucosa-lined nares, separated by the anterior cartilage of the septum. Superiorly, the nasal bones create the bridge of the nose. With the head held in a neutral upright position, the floor of the nose is perpendicular to the ground and leads back into the nasopharynx, passing the turbinates laterally and bony septum mediially. The ethmoid bone lies superiorly and crosses midline, behind the nasal bridge, to form the superior portion of the bony nasal septum and cribiform plate. The vomer makes up the inferior portion of the bony septum, and the palatine process of the maxillary bone forms the posterior floor of the nose and hard palate.

Air-containing sinuses are structural features unique to the facial skeleton. They warm and humidify inhaled air and form chambers that create the unique tone of the human voice. These sinuses develop over the period of human growth. At birth, only the ethmoid air cells and mastoid antrum are aerated. The sphenoid sinus and remainder of the mastoid air cells become aerated at approximately age 3 years. Frontal sinuses form at approximately age 6 years, and maxillary sinuses are not fully developed until age 10 years.

**Mouth**

The mouth serves as an entryway for the respiratory and gastrointestinal tracts. With the mouth in the closed position, the tongue
fills the oral cavity. Single rows of teeth lie within the alveolar ridges of the maxilla and mandible. With the mouth closed, the teeth in normal individuals occlude, with the lower row lying just internal to the upper row. The “usual” occlusion for individuals varies widely; the patient’s perception may be the best determinant of whether or not the teeth are meeting as usual. Anterior to the teeth is the vestibule, a fold of mucosa and flexible soft tissue that allows the lips to remain closed while various motor movements occur behind them. The mandible is a U-shaped bone that forms the chin and completes the lower facial skeleton. Containing the lower row of teeth, the body of the mandible meets in midline at the symphysis, which is completely fused by age 2 years. Posterior to the last molar, the bone turns to form the angle of the jaw and continues upward as the ramus of the mandible. At the most superior point of the ramus is the articular surface of the condyle, separated from the superior surface of the temporomandibular joint (TMJ) by an intervening meniscus of fibrocartilage. Anterior to the condyle lies a thin projection, the coronoid process, which provides the insertion point for the temporal muscle.

**Temporomandibular Joint**

The TMJ is complex, with the condyle of the mandible undergoing rotation and translation anteriorly during normal mouth opening. The function of the TMJ is preserved by a meniscus, which overlies the condyle. Essentially, the joint between the meniscus and condyle is a hinged joint, allowing rotation, and the joint between the meniscus and temporal bone is a sliding joint, allowing translation. A formal, thick joint capsule does not exist at the anteromedial portion of the joint; loose, relatively weak synovial tissue is positioned here to allow translation to occur.

**Soft Tissue, Vasculature, and Specialized Glands**

The skin of the face is among the thinnest of the body, draping over the underlying musculature. Facial skin falls visibly into predictable creases with age, following Langer’s lines (Fig. 35.2). At the mouth, nares, and palpebral fissures, the skin is contiguous with the mucosa lining these structures. The skin of the lips is particularly thin and lined with vascular papillae, which give the lips their vermilion hue. Lips are particularly important as part of communication; understanding their movement can allow language without sound (lip reading).

The face is a highly vascular structure, which can have grave implications for the treatment of facial injuries. With the exception of the ophthalmic artery, the superficial blood supply comes from the external carotid artery via the facial, superficial temporal, and maxillary arteries (Fig. 35.3). Soft tissue injuries and fractures that involve these vessels can lead to significant hematomas or exsanguinations. Because the face has extensive anastomotic connections across the midline and between arterial territories, however, ligation of major branches causes minimal ischemia.

Buried within the structure of the face are a series of glandular structures and ducts that are susceptible to injury. In the eye, the lacrimal glands lie within the orbits, superior and lateral to the globes, and secrete tears through ductules into the folds of the conjunctiva. The liquid flows medially into the puncta of the lacrimal canaliculi and drains into the lacrimal sac and then, via the nasolacrimal duct, into the nasopharynx.

The salivary system consists of the parotid, sublingual, and submandibular glands. The parotid is the largest of these glands, lying just anterior to the ear and wrapping around the mandible. The parotid is superficial to the masseter muscle and drains via Stensen’s duct, a 5-cm tube that curves around the anterior edge of the masseter to enter the mouth opposite the second upper molar. In normal subjects, this duct is large enough to be palpated with the masseter clenched (Fig. 35.4). The sublingual glands lie entirely within the floor of the mouth and drain into the mouth via ductules. They surround the ducts draining the submandibular glands (Wharton’s ducts). The body of the submandibular gland is folded around the mylohyoid muscle so that a portion lies within the floor of the mouth and a portion lies external to it. The submandibular (Wharton’s) ducts run from the external portion of the gland to empty into the mouth on either side of the frenulum of the tongue.

**Pathophysiology**

The basic mechanism of all injury is the transfer of energy, most often kinetic, to the structures of the body. When the energy overcomes the tolerance of the underlying tissue, injury results. Trauma traditionally has been classified as blunt or penetrating, but in many cases the effect is a combination of the two, such as the forehead injury (contusion and complex laceration) resulting from a child’s fall against the sharp corner of a coffee table. The likelihood of injury is related to the amount of energy transferred and condition of the underlying tissue. Significant injury
may result when an 80-year-old falls from standing to a carpeted floor, but it is more likely to result when the face strikes the steering wheel or dashboard in a high-speed motor vehicle collision (MVC).

The mechanism can be broken down into low-energy events, such as a fall from standing or walking into the corner of a piece of furniture, and high-energy events, such as an MVC. Understanding the mechanism of injury can help predict not only the severity of the facial injury but also the risk of associated cervical or brain injuries.

Traditional teaching had been that the face protects the brain from injury, and that patients with facial trauma are less likely to have a significant brain injury. This does not appear to be correct. Instead, recent work has suggested a significant increase in risk for brain injury among blunt trauma patients with facial fractures.11-13

The association between cervical injury and facial injury is unclear. The traditional teaching has been that the presence of a facial injury should increase the suspicion of an injury to the cervical spine. However, most of the studies supporting this idea are assessments of the incidence of cervical spine injury in patients with facial injury.14 When more sophisticated methods are used to assess any association between the two while correcting for the mechanism of injury, patients with facial injury appear to be less likely to have a significant cord injury, and there is no relationship with bony spinal injury. In the setting of multiple facial fractures, a large study of over 1 million trauma subjects in the United States and Puerto Rico found cervical spine injury prevalence ranged from 7% to 11%, whereas with an isolated facial injury, cervical spine injury ranged from 4.9% to 8%.15 Thus, in a particular patient, cervical and brain injuries should be considered based on the mechanism of injury and presentation of the patient without allowing the presence or absence of a facial injury to change the level of suspicion.

Penetrating trauma to the face from gunshots, stab wounds, blast debris, or impalement is often obvious and dramatic (Fig. 35.5). The astute emergency clinician should search avidly for...
swelling should be imaged radiographically. Assessment of bony integrity includes testing for a possible Le Fort fracture. The upper incisors are grasped and pulled anteriorly. Movement of the upper alveolar ridge (type I), midface (type II), or entire face (type III) indicates a fracture (Fig. 35.6). Wounds may need to be palpated for underlying bony injury or foreign objects; anesthesia may be required for a thorough examination within the wound. Complex lacerations involving the cartilage of the nose or ear, eyelids, lacrimal apparatus, eyebrows, or vermilion border of the lips should be identified because their repair requires special techniques.

Eyes and Orbits. In addition to the examination of lacerations and contusions, the face should be evaluated for symmetry. The appearance of the zygomata may be evaluated by looking at the patient from above. This technique also draws attention to the relative position of the eyeballs. Orbital fractures may result in enophthalmos, and a large retrobulbar hematoma (Fig. 35.7) may cause exophthalmos. The anterior chamber of the globe should

Fig. 35.6. Le Fort classification. Le Fort type 1 is shaded in red, Le Fort type II is shaded in green, and Le Fort type III is shaded in blue.
Ears. Otoscopy is performed to evaluate the integrity of the external canal, look for hemotympanum, and assess for otorrhea. Clear fluid from the ear after trauma should raise the possibility of a cerebrospinal fluid (CSF) leak. At the bedside, a drop of the fluid may be placed onto filter paper. A rapidly advancing halo of clear fluid around red blood defines a positive test result. This is a quick bedside test with good sensitivity (>86%) as long as the mix is approximately 50:50 between blood and other fluid, but it does not differentiate between CSF and saline, saliva, or other clear fluids.\(^{18}\) Leaks can also be detected easily by \(\beta_2\)-transferrin electrophoretic examination, high-resolution computer tomography (HRCT), magnetic resonance cisternography with contrast, and surgical exploration; however, some of these methods can be timely, costly, or invasive.\(^{18,19}\)

The ear should be inspected for subcutaneous hematomas (Fig. 35.9) because these need to be drained.

Nose. The nose is palpated for tenderness, crepitus, or abnormal movement; then each naris is held closed in turn to ensure that the patient is able to breathe through either side. The septum should be examined visually to look for septal hematoma (Fig. 35.10), which appears as a large purple mass extending from the

![Fig. 35.7. Retrobulbar hematoma. (From Nickson C: Bashed, blind, and bulging. http://lifeinthefastlane.com/ophthalmology-befuddler-033-2.)](image)

![Fig. 35.8. Blowout fracture. A, Periorbital swelling and ecchymosis with an eyebrow laceration related to a blowout fracture. B, CT scan of a blowout fracture.](image)
epithelialization requires the creation of a new wound to remove debris later. For contusions, ice and sleeping with the head elevated may limit the degree of swelling anticipated on days 2 and 3. The patient should be cautioned to anticipate the development of periorbital swelling, ecchymosis, or both over time as a result of gravity when the primary contusion has been to the brow, forehead, or bridge of the nose.

The most appropriate person to close an open wound may be the emergency clinician or a consultant. Decisions about which wounds to close personally and which to ask a consultant to repair are based on the personal judgment of the emergency clinician. Factors that may be considered in the decision include resource availability, size, shape, depth, and location of the wound, and the time commitment that careful, cosmetic wound closure can entail for the emergency clinician in a busy emergency department (ED). The patient’s priority with facial lacerations is cosmetics, and therefore a patient may request specialty services for even minor wounds. Children and patients with behavioral problems may require sedation to allow sufficient control for a cosmetic repair. Repair of facial wounds in uncooperative patients who are acutely intoxicated may be delayed until they become sober enough to cooperate for the procedure.

After anesthesia has been achieved, wounds should be explored for depth, foreign bodies, and underlying fractures. Irrigation may not be necessary in simple, clean facial wounds closed within 6 hours. For nongapping wounds smaller than 3 cm, a single-layer closure may be sufficient. 

For gaping wounds deeper than the dermis, subcuticular buried sutures of absorbable materials should be placed to close any potential space and relieve any tension on the skin. For skin closure, tissue adhesive is faster and less painful, results in equal cosmetic results in adults and children, and can be used to close the skin over deeper sutures. Compared with sutures, tissue adhesive has the additional benefit of not requiring later removal, but care must be taken not to glue the eye, nares, or mouth closed unintentionally.

Antibiotics are not required for simple facial wounds, which rarely become infected. Bite wounds, wounds with any evidence of devascularization, wounds through and through the buccal mucosa, wounds involving the cartilage of the ear or nose, and wounds with extensive contamination (particularly with barnyard or fecal matter) are exceptions to this rule.

The choice of antibiotic therapy will likely be an evolving topic in light of the emergence of community-associated, methicillin-resistant Staphylococcus aureus (CA-MRSA). Among spontaneous skin infections requiring an ED visit, the prevalence of CA-MRSA is now significant for adults and children. In addition, it appears that the incidence of such spontaneous infections requiring ED care is also increasing. However, current literature does not suggest choosing antibiotics with MRSA coverage for wound prophylaxis. If prophylactic antibiotic therapy is needed, the antibiotic should be selected based on the normal bacterial flora associated with the affected site.

**Mouth**

Lip lacerations are common and require special consideration to maintain the appearance of the lip edge or vermilion border and natural architecture of the philtrum. Because infiltration of even a small volume of local anesthetic may distort and blanch the soft tissue, marking the vermilion border (with nonpermanent ink or a scratch of a sterile needle) before anesthesia facilitates a cosmetic repair. To minimize any divots and maximize cosmesis and function, wounds that include the muscular layer should be closed in multiple layers. Skin may be closed with nylon or other nonabsorbable sutures; the lip and mucosa should be closed with absorbable sutures. Lip lacerations are not amenable to closure with wound adhesives.
Through-and-through lacerations of the mouth should be closed in layers, beginning with the intraoral mucosa and working outward in layers toward the skin. After closure of the mucosal layer, copious irrigation of the external wound is indicated to remove lingering bacteria that otherwise would be incorporated into the wound. Prophylactic treatment with penicillin has been shown to decrease the risk of infection after significant through-and-through lacerations. Lacerations that approach the parotid (Stensen’s) or submandibular (Wharton’s) duct should be evaluated before intervention for ductal integrity. Saliva milked from the gland should be thin and clear and exit the duct readily. If a duct is involved or there is any doubt, a facial specialist should be consulted for evaluation and repair.

Small lacerations of the tongue or oral mucosa do not require repair. Lacerations that gape (including deep tongue lacerations), collect food, and are likely to heal with a significant divot or thick scar that may hinder eating and speaking functions require repair. Deep or gaping lacerations of the tongue or oral mucosa should be closed (in layers, if necessary) with absorbable sutures that do not require removal. To facilitate repair, an assistant may be needed to expose the laceration by grasping the tongue between gauze and holding a segment outside the mouth. Some advocate placing a thick temporary suture through the distal tongue (after appropriate anesthesia) to facilitate this exposure. Discharge instructions for intraoral lacerations, whether or not they are repaired, should include gentle cleansing (swish and spit) with a mild antiseptic.

Perioral Burns

Young children use their mouths to explore their environment and may lick electrical outlets or bite electrical cords. The wet oral mucosa provides little electrical resistance, and the current penetrates to deeper structures, often causing a partial or full-thickness burn at the commissure of the lip. These children need a systemic evaluation for other electrical injuries (see Chapter 134); this discussion is limited to the evaluation and treatment of facial wounds. Perioral burns resulting from electrical injury can result in severe cosmetic problems and microstomia. The initial appearance of the wound may be misleadingly trivial; edema and necrosis progress over several days and, even with healing, the defect may become disfiguring. Traditionally, a more acute concern has been bleeding from the labial artery when the maturing burn eschar separates from underlying structures about 4 weeks postburn, and it was previously recommended that patients be admitted for close monitoring. In general, current practice is discharge with close observation at home and follow-up with otolaryngology specialists, plastic surgery specialists, or both to address cosmesis. Large wounds can cause significant early difficulty with eating, however, and patients may require placement of a nasogastric tube for the maintenance of nutrition. Initial ED treatment of the wound aims at treating discomfort and keeping the area clean.

Treatment of these injuries include early oral splinting (microstomia prevention appliance) and minimal surgical debridement, followed by scar revision and excision of the burned area at 1-year postsurgery.

Contusions of the cheek should raise concern for an underlying zygomatic or maxillary fracture. Lacerations of the lateral cheek may involve the parotid gland or Stensen’s duct. Failure to identify and repair ductal injury results in retention of salivary fluid and enlargement of the gland or formation of a cutaneous fistula. Lacerations in the area anterior to the tragus may include injury to the facial nerve, and a careful neurologic examination should be carried out before closure. Langer’s lines change from mostly horizontal in the superior cheek to diagonal at the nasolabial fold, then curve convexly around the mouth; these changes should be taken into consideration when débridement is required as part of a complex repair.

Nose

Because of its anterior position, soft tissue injuries to the nose are common. Almost any trauma can result in epistaxis. In general, epistaxis is controllable by pinching the cartilaginous anterior nose closed between two fingers and holding compression for approximately 10 minutes. If it is not controlled, anterior packing is indicated. Intranasal inspection is required in any nasal injury to assess for a septal hematoma, which appears as a dark purple or bluish mass against the septum. Hematomas require drainage because they are associated with necrosis of the septum if left untreated. Simple incision and expression of the clot followed by anterior packing are sufficient. Traditional teaching has been that any patient with nasal packing should receive prophylactic antibiotics to cover *Staphylococcus* and *Streptococcus* spp. to prevent sinusitis and toxic shock syndrome. Toxic shock syndrome is a rare but measurable complication of postoperative nasal packing, occurring in approximately 16/100,000 cases; the incidence with primary packing is unknown. There is no evidence that prophylactic antibiotics change the risk of developing toxic shock syndrome or sinusitis in postoperative or primary packing; the few studies that have been done have had sample sizes far too small to show an effect. Based on this, systemic prophylactic antibiotics are unnecessary with nasal packing. A topical antibiotic, such as chlorhexidine-neomycin (Naseptin), could be used and is a more cost-effective alternative.23

Because of the location and structure of the nasal bridge, fractures of the thin bones of this area are common. Patients with contusion or tenderness over the bridge of the nose may be assumed to have a fracture of the nasal bones. If the nose is acceptably straight on initial evaluation, there is no septal hematoma, epistaxis is controlled, and the patient is able to breathe out of each naris, no further evaluation is required emergently for isolated nasal injuries. Although radiographs of the nasal bones are still in use, they have no clinical value.26,27

Swelling over the bridge often precludes determination of the acceptability of the appearance at the time of injury. The patient may be provided with a referral for outpatient specialty follow-up in 3 to 5 days if the appearance at that time, when the swelling has improved, is unacceptable. In a series of surgically repaired simple nasal bone fractures, septal fractures were present in more than 50% of cases. CT did not provide any advantage in diagnosing septal fractures and should be reserved for evaluating patients suspected of having other, more complex fractures.28-29

Children with nasal fractures may have premature closure of sutures and uneven growth, particularly of the vomeroseptal line. In a child, no imaging studies are indicated, but a consultant should evaluate swelling and tenderness over the nose, preferably within 4 days of the injury.20

Simple lacerations of the nasal skin may be closed with sutures or tissue adhesive. If needed, anesthesia may be achieved with a nerve block of the infraorbital or supratrochlear nerves. The large pores typically present in the area of the nasal ala increase the likelihood of stitch abscesses after laceration closure in this area. Closure with an absorbable running subcuticular suture may limit the risk of this outcome. If involved, the cartilaginous portions of the ala should be closed in a separate layer with absorbable 4-0 sutures. For lacerations through and through the nose, repair
Ears
Blunt trauma to the ear may cause hematoma formation in the subperichondrial potential space. Such hematomas are the prelude to the development of a so-called cauliflower ear and should be drained by aspiration. Re-accumulation of the hematoma is prevented with a compressive dressing of the ear, but reexamination is crucial, and re-aspiration should be performed as necessary.

Ear lacerations often involve the cartilage. The ear may be anesthetized with a field block; 1% lidocaine without epinephrine can be used as a local anesthetic for direct infiltration of the ear. 1% lidocaine with epinephrine can be utilized for a regional block. Simple skin wounds may be closed in a single layer. Lacerations to the underlying cartilage should be repaired with absorbable material. If there is significant degloving or loss of overlying tissue, a consultant should be involved; portions of aural cartilage may be saved temporarily in a distant dermal pocket for later reconstruction. Because cartilage is avascular, chondritis, when it occurs, requires extensive débridement and is disfiguring. No randomized trials have been performed, but when the cartilage of the pinna requires repair, antibiotic prophylaxis covering typical skin flora as well as *Pseudomonas* is recommended. Compressive ear dressings (splints) are indicated after any significant repair. Ear injuries occurring before age 1 year or injuries to both ears in children are rare and should raise the suspicion of abuse.30

Eyes
Simple eyelid lacerations may be repaired in a single layer. Wound adhesives should be used with great caution anywhere near the eye; care must be taken not to glue the eyelids open or shut. Lacerations that involve deeper structures, loss of tissue, or the lid margin should be referred to a consultant. The integrity of the lacrimal apparatus can be assessed by instilling fluorescein into the eye and assessing for dye in the wound. A consultant should handle any injury to the sac or lacrimal duct.

Eyebrow lacerations are common because of the overhanging supraorbital ridge. Careful wound exploration should be performed to assess the integrity of the underlying bony structure. No shaving should be performed because the brow hairs may not regrow, and the hairs are necessary for realignment. If débridement is required, it should be done parallel to the hair follicles (skived) rather than perpendicular to the skin. This approach minimizes the bald area of the scar. Closing the deeper muscular layers preserves the normal expressive function of the brow. Injuries to the globe are discussed in Chapter 71.

Fractures and Dislocations
For the emergency clinician, the key to facial fractures is accurate diagnosis and appropriate referral. Many nondisplaced or minimally displaced facial fractures may be handled on an outpatient basis, with definitive repair or fixation delayed several days. In adults, fractures develop firm fibrous union within approximately 10 to 14 days; however, definitive repair is performed most easily before day 7. Fractures to the face of young children are relatively rare and may be incomplete or greenstick fractures. Fibrous union in these cases is rapid; early reduction (within 3 days) is recommended.

Broad-spectrum antibiotics against the typical sinus and nasal pathogens are indicated for open fractures and fractures that violate a sinus. Patients with fractures through the nasoethmoid (NOE) complex that violate the maxillary bones or floor of the orbit should be cautioned to avoid sneezing and blowing the nose because these activities force air out into the soft tissues of the face.

Surgical repair of simple nasal fractures may be performed closed and the nose splinted internally or packed. Repair of fractures of the floor of the orbit, when necessary, may require the placement of a silicone patch to occlude the opening into the maxillary sinus. Operative repair of most other fractures of the face is performed with the use of small metal plates (microplates), screws, or wires to stabilize fragments by attaching them to unbroken segments of bone. Efforts are made to return the features to their unfractured locations and to regain facial symmetry, if possible. Complex facial fractures may have to be repaired in a staged fashion, depending on the patient’s degree of illness and amount and quality of the bone remaining. Much of this surgery is best accomplished when the fragments are still freely mobile but initial swelling has been reduced, on postinjury days 3 to 5.

Forehead
Fractures through the superior forehead may occur above the level of the frontal sinus. These are actually skull fractures rather than facial fractures and should be addressed with special attention to risk of injury to the underlying brain. Unlike other skull fractures, frontal skull fractures often require repair for cosmesis alone. More often, fractures in this area involve the anterior portion of the frontal sinus. If even minimally displaced, these fractures require elevation for cosmesis. Fractures through the anterior wall of the frontal sinus are likely to continue through the posterior wall, and CT should be performed to look carefully for this complication; if present, a CSF leak should be assumed until proved otherwise. CSF leaks into the frontal sinus may also manifest in a delayed manner, days or years after the initial injury; with many frontal sinus fractures, complex repair or obliteration may be required to treat this complication.37

Orbit
The most common simple fracture of the orbit is a blow-out fracture of the orbital floor, often caused by a fist to blow or ball striking the globe, increasing intraorbital pressure enough to force orbital contents through the floor. This injury may happen without other significant bony facial injury. When displaced, the bony fragments sag into the underlying maxillary sinus. If the inferior rectus muscle is entrapped in the defect, the patient is unable to elevate the globe on the affected side, resulting in diplopia on upward gaze. Stretch or compression of the infraorbital nerve, which passes through the floor, may cause anesthesia over the anteromedial cheek and upper lip. Because signs of entrapment may result from contusion and edema and be self-limited, immediate repair is not necessary, but careful follow-up is required. Repair typically is performed 1 or 2 weeks after the injury for persistent enophthalmos or diplopia. Because of the acute limitation in the visual field, discharge instructions for patients with acute diplopia should include patching for comfort and a request not to drive until the diplopia is resolved.

Fractures of the medial orbital wall, through the lamina papyracea, are often associated with nasal injury or a more general midface fracture, particularly with telescoping of the midfacial skeleton. Herniation of orbital contents into the ethmoids may occur. Patients with orbital fractures with a medial component are more likely to have ocular signs of diplopia or exophthalmos than patients with fractures that did not involve the medial wall. Fractures involving the superior orbit include the base of the frontal sinus, and all the concerns about the anterior skull mentioned previously apply. Herniation of orbital structures into the frontal sinus is rare but can occur.
Many orbital fractures involve more than one wall of the orbit and may be present in a constellation with complex midface fractures (Fig. 35.11). Several classification schemes aimed at improving communication among emergency clinicians, radiologists, and maxillofacial surgeons have been proposed, but no classification system has been generally accepted.

Injury to the orbit, particularly fractures, can cause a hematoma to form within the orbit, behind the globe. If significant in size, a retro-orbital hematoma can elevate retro-orbital pressure, causing acute exophthalmos and a compartment syndrome of the retro-orbital space. Stretch on the retinal artery limiting flow to the retina or neurapraxia of the retinal nerve may cause decreased visual acuity or blindness. Orbital emphysema (Fig. 35.12) associated with fractures of the medial wall or floor rarely results in a space-filling lesion with the same effect. This is a true emergency; drainage of the air or blood via lateral canthotomy with cantholysis is indicated to save the patient’s vision. Needle aspiration of entrapped air may also be attempted, but this may be best left to a consultant, given the proximity of the globe.

Midface

Tripod (or trimalar) fractures are among the simplest fractures of the midface and include fractures of three bones—the lateral orbit, zygoma, and maxilla (Fig. 35.13). Typically caused by a direct blow, these fractures are often displaced and require operative stabilization. If left untreated, the area may sink posteriorly and inferiorly, giving an unacceptable appearance of facial asymmetry emphasized by the inferior position of the orbit and malar flattening. On the initial physical examination, there may be a large contusion over the cheekbone, enophthalmos, or malocclusion of the upper teeth. Fractures through the anterior wall of the maxillary sinus may denervate the maxillary teeth because the dentoalveolar nerves run in tunnels in this area.

More complex fractures of the midface are classified with the Le Fort system, although many complex fractures defy this simple system. Other classification systems exist. One system has divided the face into a matrix of vertical and horizontal beams to describe the fracture patterns. Another system has utilized CT findings to describe low- and high-impact fractures. Despite the Le Fort system’s limitations in describing comminuted, complex fracture patterns, it is still the most accepted classification method used. All Le Fort fractures involve the pterygoid plate, and the injury pattern can be unilateral, bilateral, or a combination. A Le Fort I fracture involves a transverse fracture through the maxilla above the roots of the teeth and may be unilateral or bilateral. Patients may report malocclusion, and the maxilla may be mobile when the upper teeth are grasped and rocked. A Le Fort II fracture is typically bilateral and pyramidal in shape. It extends superiorly in the midface to include fractures of the nasal bridge, maxilla, lacrimal bones, orbital floor, and rim. In these cases, the nasal complex moves as a unit with the maxilla when the teeth are grasped and rocked. In the current age of CT scanning, in which the full extent of comminution can be appreciated, simple Le Fort III fractures are rare but essentially involve fracturing of the connections between the elements of the skull and face (craniofacial dysjunction). These fractures start at the bridge of the nose, extend posteriorly along the medial wall of the orbit (ethmoids), along the floor of the orbit (maxilla), and through the lateral orbital wall, and finally break through the zygomatic arch. Intranasally, they extend through all the lesser bones to the base of the sphenoid and frequently are associated with a CSF leak.

Significant force to the bridge of the nose may fracture the deep NOE complex without creating a formal Le Fort pattern. CT is the initial test of choice in this setting. Fractures to the central portion of the ethmoid bone (cribiform plate) are likely to be associated with a CSF leak and commonly result in anosmia.

If possible, patients with a CSF leak should have the head elevated 40 to 60 degrees. Head elevation minimizes the intracranial
pressure, with the idea of decreasing the flow and allowing the leak to seal. Often, these patients are treated with antibiotics; however, this practice is controversial, and most of the studies supporting it involve small, local case series. Although the evidence is equivocal, it is recommended that appropriate prophylactic antibiotics be used in patients who may be immunosuppressed, have an indwelling device, or have an open contaminated wound. Neurosurgeons should be involved in the care of patients with CSF leaks, although many leaks will resolve spontaneously.18,31

Fractures involving the deeper structures of the midface may be associated with significant bleeding into the nose or oropharynx. Anterior nasal packing may be performed safely in the adult patient with multiple trauma. Even a 10-cm anterior pack should not reach the skull base in a skeletally mature person. Significant or massive bleeding into the posterior nasopharynx presents a complex problem and occurs in less than 1% of patients with midface fractures. It may be treated with nasal packing and immediate fracture reduction.32 Unless the anatomy is well understood and the skull base known to be intact, the use of a long balloon catheter (Foley) should be avoided for the control of posterior bleeding. The unintended positioning of these items within the intracranial or intraspinal space during blind nasal insertion has been well documented and, when the face is grossly distorted, preinsertion measurement or other methods of preventing this outcome have not been adequately tested.32 There are no reports of the intracranial placement of commercial catheters designed for posterior epistaxis, but if the midface is significantly distorted or telescoped, they may be long enough to reach the intracranial space. An alternative method for containing posterior nasal bleeding is to provide compression by packing the area with gauze by hand from the oropharynx after intubation.

Zygoma

Isolated fractures of the zygoma are relatively rare, usually the result of a direct blow, and often displaced. Because the condyle of the mandible may disturb zygomatic fragments while moving, fractures with significant displacement are likely to result in trismus or discomfort with mouth opening. Surgical repair is usually required to return the cheekbone to an acceptable position.

Mandible

Fractures of the mandible can result from any significant force applied to its U shape. Because of its shape, multiple fractures may result from a single blow, and the fracture sites may be distant from the site of impact. Depending on the location of the fractures, the patient may have trismus (fractures of the coronoid process, neck, or rami), dental malocclusion, swelling, and tenderness intraorally or externally. Anesthesia of the lower lip may occur if there is damage to the inferior dental nerve.

Fractures of the symphysis, body, angle, or rami usually require early splinting, typically by the placement of arch bars to accomplish interdental fixation, commonly known as wiring the jaw shut. Fixation limits fracture motion, decreases the patient’s discomfort and, if the fracture is minimally displaced, may provide complete fracture care. Impacted and nondisplaced fractures occasionally are treated with only a soft diet, and fractures of the coronoid alone usually require no intervention, but these decisions should be made in consultation with an oral surgeon or other specialist. Arch bars may be placed in the ED or operating room, typically placed by a specialist. Fracture reduction may require the extraction of teeth adjacent to the fracture line. Patients with open fractures require antibiotics and usually hospitalization. When the fractures are closed and adequate stabilization can be obtained, elective operative repair can be performed as an outpatient procedure in 3 to 5 days.

In one study, 17% to 22% of pediatric patients 4 to 11 years old developed facial growth disturbances after a fractured mandible and required later orthognathic surgery for correction. Children younger than 4 or older than 11 years were much less likely to develop this complication.30 Because of the frequency of this complication, children in this age group who have sustained a blow to the chin and who have any trismus or tenderness over the TMJ should be assessed carefully with Panorex imaging for a condylar fracture and referred appropriately.

Dental and Alveolar Trauma

Trauma to the teeth may occur with or without other facial injury. In the setting of caries, tooth fractures may occur with eating relatively soft foods. Tooth fractures are classified by the Ellis system. Class I fractures involve only the enamel of the tooth, are not painful, and can await dental evaluation on an outpatient basis. Class II fractures expose the yellow dentin and may be painful. These also can await dental care but may be covered with a dressing of calcium hydroxide and aluminum foil. Class III fractures...
expose the dental pulp, seen as a red line or dot, and are exquisitely painful. These require early evaluation by a dentist or endodontist (Fig 35.14).

Sufficient energy to the area avulses teeth from their sockets. Multitrauma patients, particularly patients who are intoxicated, required to be supine for cervical spine immobilization, or neurologically impaired, should have avulsed or mostly avulsed teeth removed from the mouth and placed externally in saline as an aspiration precaution. In a critically ill multitrauma patient, avulsed teeth should be among the lowest priorities and are reimplanted only if the care of other injuries allows it, and there is no risk of aspiration if the teeth loosen.

To perform a reimplantation, the emergency clinician disturbs the socket as little as possible, gently rinses off the tooth (the root should not be wiped), and places it into the socket where it clicks into place. If the tooth is only partially avulsed, extruded, or laterally luxated, it should not be removed; it should be reimplanted or relocated. Intruded teeth should not be manipulated. Reimplantation can be painful and may require local anesthesia with a regional dental block. Alternatively, the area of a single socket may be anesthetized by placing approximately 0.5 mL of 1% lidocaine with epinephrine is used for oral nerve blocks into the buccal sulcus and gum on the outer side of the alveolar ridge. After reimplantation, the tooth requires stabilization with acrylic splinting or wiring to the adjacent teeth. Appropriate antibiotics such as penicillin and a tetanus booster shot should be given, as well as dental follow-up for possible root canal if the reimplantation does not take.

Reimplanted teeth may or may not take acutely, but it can take weeks to assess the final success of reimplantation. The extra-alveolar time, periodontal state, and storage process seem to play a critical role in the initial success. Teeth that are successfully reimplanted in 20 to 30 minutes have fewer complications, including signs of inflammation and bone resorption. Studies also have shown that age is a factor in root resorption of teeth that have been avulsed (Fig 35.15). For children, the front maxillary incisors are usually avulsed. After reimplantation, these teeth may ankylose and fail to grow out normally, requiring later extraction or orthodontic intervention for cosmesis. This situation is most common in children aged 6 to 10 years with avulsed adult teeth.

Avulsed teeth missing after significant trauma should be carefully sought, including via a chest x-ray examination. In an acute event, the patient may not recall aspirating a tooth; this is more likely if the patient is intoxicated or neurologically impaired. If the tooth is below the diaphragm on the film, it does not require retrieval. Teeth lodged in a bronchus or the esophagus require bronchoscopic or endoscopic retrieval. Aspirated teeth result in pulmonary abscess formation unless removed.

Fractures through the alveolar ridge may result in a group of teeth being dislodged and out of position, often leaning inward. These teeth require stabilization with wire or acrylic splinting after fracture reduction has returned the teeth to their correct location. The involved teeth may or may not survive after such a fracture, and careful follow-up with a dentist or oral surgeon is required (Fig. 35.15).

Temporomandibular Joint

Trauma to the TMJ may tear the meniscus or injure the collateral ligaments holding it in a normal position. This injury can cause the meniscus to fail to translate normally, resulting in clicking or popping as it catches up to the condyle or inability to open the mouth fully because the meniscus fails to translate completely. Patients without fracture but with acute pain and difficulty with mouth opening should be placed on soft foods, asked not to yawn or struggle to open their mouths widely, and referred to an oral surgeon with expertise in TMJ pathology. Pediatric patients with posttraumatic internal derangements of the TMJ are prone to asymmetry of facial growth and retrognathia.

Because of the anatomy and function of the joint, anterior dislocation of the TMJ can occur after widely yawning, laughing, kissing, singing, or other activities that involve spontaneous wide opening of the mouth. When the condyle is out, spasm of the muscles of mastication prevents spontaneous reduction. Significant trauma is more likely to cause a fracture-dislocation. Simple dislocation may be unilateral or bilateral, and the patient may report being unable to close the mouth. In unilateral dislocation, the jaw is rotated laterally away from the affected joint; bilateral dislocation causes significant protrusion of the jaw. The jaws of these patients are often open so widely that they cannot swallow their secretions and are actively drooling. Speech is often garbled by the patient’s inability to touch the tongue to the roof of the mouth or maxillary teeth. There is a depression in the area of the affected TMJ on inspection of the patient’s face.

If the mechanism of injury suggests a fracture, the area should be imaged with plain x-ray or Panorex examination before reduction is attempted. For reduction of a simple dislocation, the patient should be seated upright. For leverage to be maximized,
the best position may be for the patient to be seated in a regular chair, with the operator standing in front of the patient. As in dislocations of other joints, adequate analgesia and sedation are required for success. With the thumb or index finger placed into the buccal sulcus on either side of the mouth, the angle of the jaw is pressed downward while the symphysis is rotated (chin) upward and backward. Care should be taken not to place fingers along the crowns of the teeth; when relocation occurs, spasm of the muscles of mastication snaps the mouth shut with force. If this is the only location possible for the emergency clinician’s fingers, gauze wrappings should be placed to protect them.

**DIAGNOSTIC TESTING**

**Imaging**

The choice of imaging for facial fractures depends on the patient’s stability, patient’s ability to cooperate, and availability of various options. The two main options are plain x-ray examination for isolated injuries and CT. Fractures are better visualized with CT than with magnetic resonance imaging (MRI), so MRI is not an optimal imaging choice. In patients in whom a fracture or penetrating injury is obvious from the physical examination, HRCT is the imaging modality of choice. For a complete evaluation, CT scans of the face should include axial, coronal, and sagittal reconstructions. Interpreting facial CT scans is an art that requires attention to bones, sinuses, orbital contents, and soft tissue and is best handled by a radiologist.

CT is now the first choice for all patients in whom a midface fracture is suspected. However, when no scanner is available, and in patients with a low to moderate pretest probability of a midface or maxillary fracture and who are stable and able to cooperate, the current recommendation is for a single screening view (Water’s or occipitomental view), followed by CT if the film is positive for a fracture or air-fluid level in any sinus.

The U shape of the mandible and presence of nearby bony structures make isolating the mandible on flat film impossible. Simple radiographs of the mandible are less sensitive than Panorex radiographs and particularly tend to miss fractures of the condyle (Fig. 35.16). If available, Panorex imaging is indicated for a first episode of TMJ dislocation, isolated mandibular fractures, dental fractures, or fractures of the alveolar ridge. In children, if fracture of the condyle is suspected, coronal CT is more sensitive and specific than Panorex studies. Although the traditional teaching has been that the mandible’s shape results in two fractures if it is fractured at all, a case series using CT evaluation has found that 42% of mandibular fractures are unifocal.

For patients with complex fractures, new imaging techniques may help improve surgical planning and esthetic outcomes. In displaced orbital fractures, use of CT data to measure orbital volumes has shown that after repair, an orbital volume greater than 4% larger than on the unfractured side is associated with visible postoperative enophthalmos. This method seems to be useful in predicting which patients might benefit from operative repair. In conjunction with more standard two-dimensional facial CT scans, three-dimensional CT scans seem to improve the diagnosis and aid preoperative planning for patients with complex fractures of the midface (Fig. 35.17).

Blunt cerebrovascular injury (BCVI) incidence is still not fully known in the trauma setting. CT angiography (CTA) should be used as a screening and diagnostic tool when evaluating for BCVI. This is an evolving area in which 20% of injuries are still missed until patients become symptomatic and are often outside the therapeutic window, with devastating neurologic consequences. BCVI requires a high index of suspicion and should be considered in any patient with a cervical spine fracture, neurologic examination that does not fit the diagnostic picture, and patients with Horner’s syndrome, LeFort II or III fractures, skull base fractures, or soft tissue injuries of the neck. The gold standard for diagnosis is angiography; however, CTA should be considered as part of the initial trauma evaluation protocol (Fig. 35.18).

Patients with tenderness and swelling isolated to the bony bridge of the nose who do not have a septal hematoma, can breathe through each naris, and have a straight nose do not require nasal bone radiography in the ED because imaging results would not alter treatment. If these criteria are not met, early reduction by a specialist or referral for surgical intervention may be indicated, and evaluation by plain films (for truly isolated injuries) or CT scanning (if concern for other injuries exists) is indicated. Plain x-ray examination may also be performed in the setting of legal concerns. If there is concern for a foreign body in a superficial wound, two standard x-ray views (Water’s and Caldwell’s, or occipitofrontal view) are indicated to triangulate the position of the observed foreign material.

Patients with suspected ocular injuries may benefit from bedside ultrasound as a noninvasive and cost-effective diagnostic tool, particularly if there is a need for urgent operative management of other injuries and no time for a dedicated facial CT. One case study used bedside ultrasonography for the diagnosis of a retrobulbar hematoma and termed the findings of conical deformation of the ocular globe’s posterior aspect as the guitar pick sign. The different acoustic impedances of the orbit’s anatomic structures make this modality operator-friendly, and an ultrasound of the eye can readily detect lens dislocation, vitreous

Care of the patient with penetrating trauma to the face should center on standard trauma care, with initial attention focused on maintenance of a patent airway, adequate ventilation, and systemic perfusion.

Out-of-Hospital Care

The indications for airway management of a patient with a facial injury are the same as those for other patients. Does the patient have a currently patent airway and, if so, can the patient be expected to maintain it without intervention? If the answer to either question is “no,” the patient needs to be intubated. If other injuries preclude the patient from ventilating appropriately, intubation is also required.

Patients with expanding hematomas after facial injury present a special dilemma. Injuries to the facial vasculature may cause significant hematomas that can extend into the neck or down to the supraclavicular area. Such hematomas greatly distort the normal anatomy of the pharynx and neck, making intubation and cricothyroidotomy particularly difficult. If the patient has a patent airway, he or she can speak without difficulty, and the transport time is expected to be short, no intervention should be performed. and the receiving institution should be notified so that planning can begin for a difficult airway. If intubation must occur in the field, awake orotracheal intubation should be considered. If certified in its use, emergency medical services personnel should be ready to perform a surgical airway as needed. Gunshot wounds to the lower third of the face are particularly likely to require intubation for airway protection, and a significant proportion of these require a surgical airway.

In the setting of significant facial trauma, active bleeding can obscure the view and make intubation considerably more difficult. Double suctioning may be required, which involves an assistant holding one suction catheter in the posterior oropharynx while the operator uses a second device more anteriorly or inferiorly, as needed during the procedure. Conversely, patients with fractures of the mandible may be easier to intubate because increased mobility of the mandible may allow wider opening of the mouth.

Management of facial injuries occurs within the overall resuscitation of the patient. Unless the airway is threatened or exsanguination is a concern, treatment of most facial injuries can be deferred until more life-threatening injuries have been stabilized.

**Fig. 35.18.** CT angiography slice of the head and neck from a moped accident patient. There is no flow seen in the right internal carotid artery, suggestive of a blunt cerebrovascular injury.
Control of local bleeding is the other significant out-of-hospital consideration in facial trauma. In many areas, external compression is sufficient to control bleeding during transport. Epistaxis and significant intraoral bleeding can be more difficult to treat. Even in the setting of significant nasal trauma, the soft portions of the nares can be compressed to stop anterior nasal bleeding. In an awake alert patient with intraoral bleeding, 4 × 4-inch gauze packing may be placed into the buccal space to provide control. If these maneuvers are insufficient, and the patient’s injuries require spinal immobilization, intubation may be a necessary first step to control intraoral or nasopharyngeal bleeding. After

**LEMON Criteria**

L = Look externally (facial trauma, large incisors, beard or mustache, large tongue)

E = Evaluate the 3-3-2 rule (incisor distance, 3 fingerbreadths; hyoid-mental distance, 3 fingerbreadths; thyroid to mouth distance, 2 fingerbreadths)

M = Mallampati (Mallampati score > 3)

O = Obstruction (presence of any condition such as epiglottitis, peritonsillar abscess, trauma)

N = Neck mobility (limited neck mobility)

*Patients in the difficult intubation group have higher LEMON scores.*

or anesthesiology-assisted intubations with the use of adjuncts such as the GlideScope or lighted stylet.44-51

Control of local bleeding is the other significant out-of-hospital consideration in facial trauma. In many areas, external compression is sufficient to control bleeding during transport. Epistaxis and significant intraoral bleeding can be more difficult to treat. Even in the setting of significant nasal trauma, the soft portions of the nares can be compressed to stop anterior nasal bleeding. In an awake alert patient with intraoral bleeding, 4 × 4-inch gauze packing may be placed into the buccal space to provide control. If these maneuvers are insufficient, and the patient’s injuries require spinal immobilization, intubation may be a necessary first step to control intraoral or nasopharyngeal bleeding. After
intubation, large amounts of gauze can be placed via the mouth into the oropharynx and nasopharynx to obtain control via direct pressure.

If out-of-hospital personnel suspect a ruptured globe, special protection against compression of the eye (eg, eye cup, noncontact shielding) should be provided in the field. Avulsed parts, including the ears, tip of the nose, teeth, or completely avulsed flaps, should be transported with the patient in saline-soaked gauze.

Completely avulsed teeth should be removed and carried with the patient during transport. Neurologically normal, nonintoxicated patients may be able to carry avulsed teeth in their mouths, held between the gum and buccal mucosa. Patients who are not neurologically normal, are intoxicated, require cervical spine immobilization, are nauseated, or cannot be transported upright should not be transported with avulsed teeth held in the mouth. In such cases, the risk of aspirating the teeth outweighs any other concerns, and the teeth should be transported in a container with sterile saline. Incompletely avulsed teeth should be left in place and not manipulated.

**Emergency Department Treatment**

**General Measures**

The initial evaluation in the ED should re-address the question of intubation. In the setting of significant distortion of the mouth, oropharynx, or upper neck by avulsion or hemotoma, the awake fiberoptic method may optimize the chances of a successful intubation. When there is significant distortion of the oropharynx or larynx, a laryngeal mask airway may not achieve a sufficiently tight fit to allow ventilation. Emergent cricothyroidotomy is the procedure of choice if endotracheal intubation is impossible.

Unless there is life-threatening hemorrhage from the face, facial injuries can be safely left to the secondary survey after the airway has been secured. The emergency clinician should avoid being distracted by a facial injury and search intensively for head, neck, chest, abdominal, pelvic, and extremity injuries. In-depth ocular examinations and other special testing should not be performed until other serious injuries have been managed emergently.

Significant bleeding can often be controlled by compression. If compression fails, hemostasis can be achieved in the ED by ligation of the relevant vessel. Great care should be taken, however, not to clamp or tie structures blindly deep within the face because serious iatrogenic injury of nerve or ductal structures could result. Massive uncontrollable bleeding from facial fractures occurs rarely and is best treated with arterial embolization, if available.\(^52\)

Intraarterial vasopressin has recently been suggested as an option for hemostasis.\(^52\) Tranexamic acid may also show promise in controlling hemorrhage from facial trauma.\(^29\)

In the rare case of a patient acutely exsanguinating from a facial wound, the external carotid artery can be emergently ligated. This ligation is best accomplished with surgical assistance.

Bite wounds, gross contamination, or significant tattooing from foreign bodies should be addressed definitively as soon as possible, given the needs of the patient’s other injuries. Definitive treatment of simple soft tissue injuries can be left for 24 hours, if needed, after irrigation and temporary approximation. Ideally, facial fractures are treated early, before significant swelling occurs, or after several days, when return of more normal facial contours can aid in the repair. The need for tetanus prophylaxis should be considered for all open wounds. If the injury is an animal bite, the need for rabies prophylaxis should be considered. Because the rabies virus is transmitted to the brain along nerve axons, and symptomatic disease theoretically may occur sooner with wounds of the head, face, and neck, initiating rabies treatment within 5 days of the injury is recommended.

Because lead poisoning has been reported from the ingestion of shotgun pellets in patients with primarily facial injuries, consideration should be given to looking for the presence of pellets in the gastrointestinal tracts of these victims. A plain x-ray film of the abdomen suffices. Early endoscopic removal of the pellets should limit future toxicity.

The final part of the physical examination when dealing with facial trauma is the importance of documentation. Facial injuries may be evidence of assault, domestic violence, or child abuse. Careful documentation of findings, including photographs, drawings, or both, not only communicates initial findings to other practitioners but also can provide crucial legal evidence because many of these cases have forensic implications or result in litigation.

**DISPOSITION**

The decision to discharge or admit patients with facial trauma depends on their associated injuries, general injury severity, and plans for treatment. In general, the emergency clinician can handle the initial resuscitation and stabilization of patients with facial trauma. It is recommended that early consultation with the appropriate surgical specialists happen once the patient has been stabilized. Antibiotics should be considered in cases of severe facial trauma or open fractures. Patients with isolated facial trauma that has been repaired or stabilized and with no airway issues are usually discharged with close follow-up.

**KEY CONCEPTS**

The face is central to the patient’s ability to breathe, eat, and communicate. Injuries to the face can have serious psychological and psychosocial consequences.

- Facial injuries may be prevented by the appropriate use of seat belts, child restraints, air bags, helmets, and mouth and face guards.
- The epidemiology of facial injury is changing, with an increasing proportion of injuries occurring as a result of interpersonal violence. A careful history is required, and the possibility of abuse should be considered for every patient.
- Shock from facial trauma is rare and results only from obvious external bleeding. Facial injuries should not distract the emergency clinician from aggressively searching for other causes of shock.
- Assertive management of the airway is indicated in a patient with significant facial injuries. Surgical management (cricothyroidotomy) may be required, particularly with gunshot wounds.
- Directed facial CT scanning is the best imaging technique in patients with obvious injuries.
- Definitive treatment may be delayed, if necessary, to allow other serious injuries to be addressed.

REFERENCES

Tripod (or trimalar) fractures are among the simplest fractures of the midface and include fractures of three bones—the lateral orbit, zygoma, and maxilla. More complex fractures of the midface are classified using the Le Fort system, although many complex fractures defy classification with this system. A Le Fort I fracture involves a transverse fracture through the maxilla above the roots of the teeth and may be unilateral or bilateral. Patients may complain of malocclusion, and the maxilla may be mobile when the upper teeth are grasped and rocked. A Le Fort II fracture is typically bilateral and pyramidal in shape. It extends superiorly in the midface to include the fracture of the nasal bridge, maxilla, lacrimal bones, orbital floor, and rim. In these cases, the nasal complex moves as a unit with the maxilla when the teeth are grasped and rocked. Le Fort III fractures involve fracturing the connections between the elements of the skull and face (craniofacial disjunction). These fractures start at the bridge of the nose and extend posteriorly along the medial wall of the orbit (ethmoids), along the floor of the orbit (maxilla) and through the lateral orbital wall, and finally break through the zygomatic arch. Intranasally, they extend through all the lesser bones to the base of the sphenoid and frequently are associated with a cerebrospinal fluid (CSF) leak.

35.3. Treatment for a patient with a blowout fracture can include all the following recommendations except which one?
A. Application of cold compress to reduce swelling
B. Appropriate oral antibiotic
C. Discouraging nose blowing to avoid creating or exacerbating any orbital emphysema
D. Use of decongestants to help keep the sinuses clear of any draining fluid
E. Use of steroid eye drops to help decrease any inflammation in the affected eye

Answer: A. The use of steroid eye drops should not be initiated by the emergency clinician for a blowout fracture. Antibiotic prophylaxis against the potential sequelae of sinusitis, orbital cellulitis, and other more malignant intracranial infections is appropriate, as would be the use of decongestants and the avoidance of any activities that would exacerbate orbital emphysema.
PRINCIPLES

Background and Importance

According to the National Spinal Cord Injury Statistical Center, motor vehicle collisions (MVCs) account for 37% of all spinal injuries.1 Speeding, alcohol intoxication, and failure to use restraints are major risk factors. The next most common cause of spinal cord injury (SCI) is falls, followed by acts of violence (primarily gunshot wounds) and sporting activities. Approximately 80% of victims are male, and the average age at injury is 42.6 years. The lifetime cost to care for SCI victims ranges from $1 million if older than 50 years, with incomplete motor function, to over $4 million for those younger than 25 years, with complete paraplegia. The total cost to society from lifelong medical expenses and lost productivity for all ages and types of spinal injuries is estimated to be more than $5 billion. The devastating emotional and psychological impact is incalculable.

Injuries of the soft tissues supporting the cervical spine can result in chronic pain and disability. The term whiplash-associated disorder (WAD) has been used to describe these injuries because of the flexion-extension movement of the neck that results from rear-end MVCs, the most common cause of a WAD. Due to the large number of people sustaining these injuries, the annual costs associated with a WAD exceed $230 billion, which is more than the combined costs associated with spinal cord and brain injuries caused by MVCs.2

Anatomy and Physiology

The human spine consists of 33 bony vertebrae—7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one), and 4 coccygeal (usually fused into one; Fig. 36.1). These 26 individual units are separated from one another by flexible intervertebral disks and connected to form a single functioning unit by a complex network of ligaments (Fig. 36.2). The vertebral column protects the spinal cord, which extends from the midbrain to the level of the second lumbar vertebra.

Spinal injuries involve fractures in 85% of cases. Of these, 10% are ligamentous injuries without fracture, and 5% are SCIs without a radiographic abnormality (SCIWORA), in which the spinal cord is injured directly without radiographic evidence of bony or ligamentous injury. Stability of a spinal injury refers to the resistance to displacement of fracture fragments or, in the case of ligamentous injury, the entire vertebral unit. There are several classification systems for assessing the stability of subaxial spinal column injuries, including the Allen Ferguson classification, Association for Osteosynthesis classification, Dennis Classification, and thoracolumbar injury classification and severity score for thoracolumbar injuries. According to a survey of the members of Spine Trauma Study Group of the International Spinal Cord Society, practical implementation is evenly distributed among the classification systems.3 The three parallel vertical column model proposed by Denis2 depicts the anterior column as being formed by alternating vertebral bodies and intervertebral disks surrounded by the annulus fibrosus capsule and anterior longitudinal ligament. The middle column consists of the posterior part of the annulus fibrosus and posterior vertebral wall, posterior longitudinal ligament, spinal cord, paired laminae and pedicles, articulating facets, transverse processes, nerve roots, and vertebral arteries and veins. The posterior column consists of the spinous processes, nuchal ligament, interspinous and supraspinous ligaments, and ligamentum flavum. Disruption of a single column usually preserves stability but does not preclude an SCI from displaced fracture fragments. Disruption of two columns results in an injury that is stable in one direction but unstable in another (eg, stable in flexion but unstable in extension). Disruption of all three columns produces a highly multidirectional unstable injury.

Pathophysiology

Classification of Spinal Column Injuries

Acute spinal injuries are classified according to the mechanism of trauma—flexion, flexion-rotation, extension, and vertical compression (Table 36.1).

Flexion. Pure flexion injuries involving the Cl-C2 complex can cause unstable atlanto-occipital or atlantoaxial joint dislocation, with or without an associated fracture of the odontoid (Fig. 36.3). The basion-axial interval (BAI) and basion-dens interval (BDI) are normally less than 12 mm. A value greater than 12 mm is suggestive of an atlantoaxial joint dislocation (Fig. 36.4). Calculating the ratio of the distance from the basion to midvertical portion of the posterior laminar line of the atlas over the distance from the opisthion to midvertical portion of the posterior surface of the anterior ring of the atlas (Fig. 36.5) indicates subluxation if the ratio is greater than 1. These injuries are considered unstable because of their location and the relative lack of muscle and ligamentous support.

In pure flexion injuries below C2, a longitudinal pull is exerted on the strong nuchal ligament complex, which usually remains intact. Most of the force is expended on the vertebral body anteriorly, causing a simple wedge fracture. Radiographically, there is a diminished height and increased concavity of the anterior border of the vertebral body, increased density of the vertebral body resulting from bony impaction, and prevertebral soft tissue swelling (Fig. 36.6). Because the posterior column remains intact, this injury is usually stable. However, spinal instability may occur with severe wedge fractures (loss of more than half the vertebral height) or multiple adjacent wedge fractures.

A flexion teardrop fracture results when severe flexion forces cause anterior displacement of a wedge-shaped fragment (resembling a teardrop) of the anterosuperior portion of the involved vertebral body (Fig. 36.7). This injury, which is associated with neurologic injury, is highly unstable because the anterior and posterior ligaments are commonly disrupted.

**Fig. 36.7.** A, B, Lateral view of a teardrop fracture. Mechanism—flexion; stability—unstable. The fractured fragment off the C5 body resembles a teardrop.
The clay shoveler's fracture is an oblique fracture of the base of the spinous process of one of the lower cervical vertebrae (Fig. 36.8). The injury derives its name from the fracture caused by the abrupt head flexion that clay miners experienced when lifting a heavy shovelful of clay and having the clay stick to the shovel. This force, transmitted through the supraspinous ligament, results in an avulsion fracture of the spinous process. Today, this fracture is seen after direct trauma to the spinous process and after sudden deceleration MVCs that result in forced neck flexion. Because this injury involves only the spinous process, it is stable and requires no treatment beyond symptomatic care.

Pure spinal subluxation occurs when the ligamentous complexes rupture without an associated bony injury. This injury begins posteriorly in the nuchal ligament and proceeds anteriorly to involve other ligaments (Fig. 36.9). Although rarely associated with neurologic damage, this injury is potentially unstable.

---

**Fig. 36.8.** A, B, Clay shoveler's fracture. Mechanism—flexion; stability—mechanically stable. Note the avulsed fragment off the tip of the C7 spinous process in an underpenetrated lateral view (arrow).

**Fig. 36.9.** A, B, Subluxation with bilateral perched facets at C5 and C6. Mechanism—flexion; stability—unstable. Lateral view shows severe subluxation of C5 on C6.
Bilateral facet dislocations occur when a greater force of flexion causes soft tissue disruption to continue anteriorly to the annulus fibrosis of the intervertebral disk and anterior longitudinal ligament, resulting in extreme instability. The forward movement of the spine causes the inferior articulating facets of the upper vertebra to pass upward and over the superior facets of the lower vertebra (Fig. 36.10), resulting in anterior displacement of the spine above the level of injury.

Shear Injury. Trauma to the head directed in an anteroposterior (AP) direction may result in fracture of the odontoid process above the transverse ligaments (type I) or, more commonly, at the base of the odontoid process where it attaches to C2 (type II; Fig. 36.11). Slight angulation of the force may result in extension of the fracture into the body of C2 (type III; Fig. 36.12). Type I odontoid fractures are usually stable because they are an avulsion injury to the odontoid tip. However, if traction forces injure the apical and alar ligaments, the fracture may be unstable. Type II odontoid fractures are, by definition, unstable and are often complicated by nonunion. Type III odontoid fractures are also mechanically unstable because they can extend laterally into the superior articular facet of the atlas.

Flexion-Rotation. Rotary atlantoaxial dislocation is an unstable injury visualized best on open-mouth odontoid radiographs (Fig. 36.13) or a computed tomography (CT) scan. When the x-ray image reveals symmetric basilar skull structures, a unilateral magnified lateral mass confirms a C1-C2 dislocation.

A unilateral facet dislocation is caused by both flexion and rotation. The rotational component of this injury occurs around one of the facet joints, which acts as a fulcrum. Simultaneous flexion and rotation cause the contralateral facet joint to dislocate, with the superior facet riding forward and over the tip of the inferior facet and coming to rest within the intervertebral foramen. In this position, the dislocated articular mass is mechanically locked in place, making this a stable injury even though the posterior ligament complex is disrupted.

Any cervical fracture or dislocation may cause torticollis however torticollis may also be caused by a benign process such as a muscle spasm. It may be difficult to differentiate the two.
Fig. 36.12. A–F, Odontoid fracture, type III.
which articular processes are large and nearly vertical, unilateral facet dislocation is rare. Instead, one or both articular processes fracture, and the upper vertebra swings forward. Commonly seen in the thoracolumbar and lumbar regions, this rotation fracture-dislocation is unstable (Fig. 36.16).

Extension. Fracture of the posterior neural arch of the atlas (C1) results from compression of the posterior elements between the occiput and spinous process of the axis (C2) during forced neck extension (Fig. 36.17). Although the anterior arch and transverse ligament remain intact, this fracture is potentially unstable because of its location.

The hangman's fracture, or traumatic spondylolysis of C2, occurs when the cervicocranium—the skull, atlas, and axis functioning as a unit—is hyperextended as a result of abrupt deceleration. Bilateral fractures of the pedicles of the axis occur with or without dislocation (Fig. 36.18). Although unstable, cord damage is often minimal because the AP diameter of the neural canal is greatest at C2, and the bilateral pedicular fractures permit spinal canal decompression. Originally described in victims of hanging injury, today it is most often the result of head-on MVCs.

The extension teardrop fracture occurs when abrupt extension of the neck causes the anterior longitudinal ligament to pull the anteroinferior corner of a vertebral body away from the remainder of the vertebra, producing a triangular fracture that is radiographically similar to the flexion teardrop fracture. Often occurring in lower cervical vertebrae (C5–C7) from diving accidents, this injury may be associated with a central cord syndrome (see later) and is caused by the ligamentum flavum buckling into the spinal cord. Because the posterior elements remain intact, this injury is stable in flexion but potentially unstable in extension.
Fig. 36.15. Unilateral facet dislocation. Mechanism—flexion and rotation; stability—stable. A, B, Lateral view showing one dislocated articular facet of C5 lying anterior to the corresponding facet of C6 and creating a bowtie deformity. The C5 vertebral body is subluxed anteriorly on C6. C, D, Oblique view of unilateral facet dislocation with the lamina of C6 projecting into the neural foramen. E, F, CT scan showing facet dislocation. The inferior facet (arrow) lies posterior to the superior facet.
Vertical Compression. Vertical compression injuries occur in the cervical and lumbar regions, which are capable of straightening at the time of impact. When forces are applied from above (skull) or below (pelvis or feet), one or more vertebral body endplates may fracture. The nucleus pulposus of the intervertebral disk is forced into the vertebral body, which is shattered outward, resulting in a burst fracture (Fig. 36.19). Sagittal CT cuts and a frontal radiograph will demonstrate a comminuted vertebral body, and there will typically be greater than 40% compression of the anterior vertebral body, which helps differentiate it from the simple wedge fracture. Coronal CT cuts and a frontal radiograph demonstrate a characteristic vertical fracture of the vertebral body. This is a stable fracture because all the ligaments remain intact.

Fig. 36.16. A, B, MRI scan showing fracture-dislocation of the thoracic spine.

Fig. 36.17. A, B, CT scan of posterior neural arch fracture of C1. Mechanism—extension; stability—unstable. The fracture line is well visualized.

Fig. 36.18. Hangman’s fracture. Mechanism—extension; stability—unstable. Fracture lines extending through the pedicles of C2 are well visualized. Retropharyngeal soft tissue swelling is apparent.

Fig. 36.19. Sagittal CT cuts of thoracic spine.
Rarely, vertical compression fractures may result in isolated fractures of the articular pillar or vertebral body, exhibiting vertical and oblique lines of fracture. An extremely unstable injury, the C1 Jefferson fracture occurs when a vertical compression force is transmitted through the occipital condyles to the superior articular surfaces of the lateral masses of the atlas, driving the lateral masses outward, disrupting the transverse ligament and resulting in fractures of the anterior and posterior arches of the atlas (Fig. 36.21). The lateral film may demonstrate a widening of the predental space between the anterior arch of C1 and the odontoid, or dens. The open-mouth view will demonstrate a bilateral offset of right and left lateral masses of C1 relative to the lateral masses of C2. A fracture should be diagnosed when the sum of the offset distances from the right and left sides exceeds 7 mm. However, when the fragments are minimally displaced, the Jefferson fracture is difficult to recognize.

An extremely unstable injury, the C1 Jefferson fracture occurs when a vertical compression force is transmitted through the occipital condyles to the superior articular surfaces of the lateral masses of the atlas, driving the lateral masses outward, disrupting the transverse ligament and resulting in fractures of the anterior and posterior arches of the atlas (Fig. 36.21). The lateral film may demonstrate a widening of the predental space between the anterior arch of C1 and the odontoid, or dens. The open-mouth view will demonstrate a bilateral offset of right and left lateral masses of C1 relative to the lateral masses of C2. A fracture should be diagnosed when the sum of the offset distances from the right and left sides exceeds 7 mm. However, when the fragments are minimally displaced, the Jefferson fracture is difficult to recognize.

Classification of Spinal Cord Injuries

Primary Spinal Cord Injury. The spinal cord may be injured by three broad categories of injury patterns. First, penetrating trauma or massive blunt trauma with disruption of the vertebral column causes transection of neural elements. Because neurons within the central nervous system do not regenerate, such injuries are irreversible. Less severe blunt trauma may have similar effects resulting from a displaced bony fragment or herniated disk injuring the cord.

Second, when patients with cervical osteoarthritis and spondylosis, particularly older adults, are subjected to forcible cervical
spine extension, the spinal cord may be injured secondary to compression between an arthritically enlarged anterior vertebral ridge and a posteriorly located hypertrophic ligamentum flavum (Fig. 36.22). This injury frequently results in a central cord syndrome.

The third mechanism is primary vascular damage to the spinal cord. The spinal cord may be compressed by an extradural hematoma, particularly in patients who are on anticoagulants or have bleeding disorders. Vascular injuries should also be suspected when there is a discrepancy between the clinically apparent neurologic deficit and known level of spinal injury. For example, a lower cervical dislocation may compress the vertebral arteries as they travel within the spinal foramina of the vertebrae, resulting in thrombosis of the anterior spinal artery that originates from both vertebral arteries at C1 (Fig. 36.23). On physical examination, such an injury may erroneously appear to be localized to the level of C1 or C2. Also, the great radicular artery of Adamkiewicz, originating from the aorta and entering the spinal canal at the level of L1, sends branches as cephalad as T4. Therefore, a lumbar fracture or dislocation can produce a neurologic deficit as high as T4.

**Secondary Spinal Cord Injury.** The maximum neurologic deficit after blunt spinal cord trauma is often not seen on initial examination and may, instead, progress over many hours. Studied extensively in animal models, the histopathology of secondary SCI is now thought to be due to a complex cascade of biochemical events that result in progressive ischemia of gray and white matter during the postinjury period (Fig. 36.24). Other factors, such as hypoxia, hypotension, hyperthermia, and hypoglycemia, also affect the ultimate extent of SCI.

**Classification of Cervical Soft Tissue Injuries**

Blunt force trauma can injure one or more of the soft tissues of the neck, including ligaments, muscles, intervertebral disks, zygapophysial facet joints, dorsal root ganglia, and vertebral artery. Although injuries of these tissues have been documented in biomechanical, animal, and human autopsy studies, a validated diagnostic test is only available for facet injuries.\(^4\)\(^5\) The cardinal symptom of a WAD is neck pain, but neck stiffness, neck and arm paresthesias, and dizziness are commonly reported. Table 36.2 shows the Quebec Task Force classification of WADs, the most common classification used worldwide.\(^2\)

**CLINICAL FEATURES**

**Neurologic Evaluation**

The initial neurologic evaluation of a patient with a suspected spinal injury should begin with observation. Careful inspection, beginning with the head and proceeding downward, may reveal signs of possible spinal involvement. Significant head and facial trauma have a 5% to 10% incidence of associated cervical spine injuries. Scapular contusions suggest a rotation or flexion-rotation injury of the thoracic spine. Chest and neck abrasions from...
occipital pain, whereas discomfort in the trapezius muscle, particularly in the absence of signs of local trauma, suggests a C5 injury. The past medical history is important because certain conditions predispose patients to cervical injury. For example, Down syndrome patients are predisposed to atlanto-occipital dislocation, whereas rheumatoid arthritis patients are prone to rupture of the C2 transverse ligament.

Palpation of the entire spine and paraspinal musculature may reveal areas of tenderness, deformity, or muscle spasm. A step-off may be appreciated with severe subluxation. Widening of an interspinous space indicates a tear in the posterior ligament complex and a potentially unstable spinal injury.

The motor activity of the body is complex. Because a single motion is often governed by muscles innervated by multiple spinal segments, localizing a spinal lesion based solely on motor function is extremely difficult. Testing the presence and strength of those motions outlined in Table 36.3, however, provides a rapid baseline assessment. When a deficit is noted, the motor and neurologic examination should be repeated because progression of dysfunction may occur. Even the most minimal of motor

automobile shoulder belts and lower abdominal markings from lap belts indicate possible blunt carotid and vertebral injuries, as well as spinal, intrathoracic, and intra-abdominal injuries. As occurs with falls from considerable heights, injuries to the gluteal region, calcaneal fractures, and severe ankle fractures suggest a compression type of spinal injury.

Because the diaphragm is innervated by the phrenic nerve, which originates at C3-C4, an abdominal breathing pattern may provide an important clue to an upper cervical injury. The presence of Horner’s syndrome, characterized by unilateral ptosis, miosis, and anhidrosis, may result from disruption of the cervical sympathetic chain, usually between C7 and T2. Priapism may occur with severe SCI, and it is often associated with spinal shock, which is a transient reflex depression of the spinal cord below the level of the injury.

The emergency clinician should speak with the patient during the examination because it provides the patient with reassurance and the emergency clinician with valuable information. Patients may experience pain in the sensory dermatome corresponding to the injured spinal level. For example, a C2 lesion may cause occipital pain, whereas discomfort in the trapezius muscle, particularly in the absence of signs of local trauma, suggests a C5 injury. The past medical history is important because certain conditions predispose patients to cervical injury. For example, Down syndrome patients are predisposed to atlanto-occipital dislocation, whereas rheumatoid arthritis patients are prone to rupture of the C2 transverse ligament.

Palpation of the entire spine and paraspinal musculature may reveal areas of tenderness, deformity, or muscle spasm. A step-off may be appreciated with severe subluxation. Widening of an interspinous space indicates a tear in the posterior ligament complex and a potentially unstable spinal injury.

The motor activity of the body is complex. Because a single motion is often governed by muscles innervated by multiple spinal segments, localizing a spinal lesion based solely on motor function is extremely difficult. Testing the presence and strength of those motions outlined in Table 36.3, however, provides a rapid baseline assessment. When a deficit is noted, the motor and neurologic examination should be repeated because progression of dysfunction may occur. Even the most minimal of motor

* Localization of lesions in this area is best accomplished with the sensory examination.
is important because the latter condition may be caused by a surgically correctable lesion. After the initial period of areflexia, reflexes gradually return after 1 to 3 days and, after 1 to 4 weeks, patients with SCI will manifest characteristic hyperreflexia and spasticity. Reflexes are typically absent during the initial phase of spinal shock in the emergency department (ED), however.

Sensory function can be quickly evaluated through the use of a structured approach (Table 36.4) or graphic dermatome chart (Fig. 36.25). After locating an area of hypesthesia, one should move the sensory stimulus from areas of decreased sensation outward, rather than the reverse, because patients are more sensitive to the appearance of sensation than to its disappearance. This test should be performed first with a cotton swab to assess sensitivity to light touch, a posterior column function. A pin should be used to assess pain, which is an anterior spinothalamic tract function. Even in the presence of complete motor paralysis, the presence of islands of preserved sensation within an affected dermatome or below the level of dysfunction indicates potential for functional recovery. An accurate baseline sensory examination is imperative because cephalad progression of hypesthesia is the most sensitive indicator of deterioration. When this is observed in the cervical region, one should anticipate impending respiratory failure and preemptively secure the airway.

Spinal Cord Lesions

**Complete Spinal Cord Lesions**

A complete spinal cord lesion is defined as total loss of motor power and sensation distal to the site of an SCI. Functional motor recovery is rare with a complete cord syndrome that persists for longer than 24 hours. Before making the diagnosis of a complete cord syndrome, however, two points should be considered. First, any evidence of minimal cord function, such as sacral sparing, excludes the patient from this group. Signs of sacral sparing include perianal sensation, preserved rectal sphincter tone, and lower extremity weakness.

Second, a complete spinal cord lesion may be mimicked by a condition termed **spinal shock**, which may persist for a few weeks. Spinal shock results from a concussive injury to the spinal cord that causes total neurologic dysfunction distal to the site of injury. The end of spinal shock is heralded by the return of the bulbocavernous reflex, which is a normal cord-mediated reflex elicited by placing a gloved finger in the patient’s rectum and then squeezing the glans penis or clitoris or by tugging gently on the Foley catheter. An intact reflex results in rectal sphincter contraction. Absence of this reflex indicates the presence of spinal shock, during which time the patient’s prognosis cannot be accurately assessed.

**Incomplete Spinal Cord Lesions**

Approximately 90% of incomplete spinal injuries can be classified as one of three clinical syndromes—the central cord syndrome, Brown-Séquard syndrome, and anterior cord syndrome (Fig. 36.26). The most common is the central cord syndrome, often seen in patients with degenerative arthritis who suffer neck hyperextension. The ligamentum flavum buckles into the cord, resulting in a concussion of the central gray matter in the pyramidal and spinothalamic tracts. Because fibers innervating distal structures are located in the spinal cord periphery, the upper extremities are more severely affected than the lower extremities. The prognosis is variable, but more than 50% of patients with central cord syndrome become ambulatory and regain bowel and bladder control, as well as some hand function.

The Brown-Séquard syndrome, or hemisection of the spinal cord, usually results from penetrating trauma but may also be seen after lateral mass fractures of the cervical spine. Patients with this lesion have ipsilateral loss of position and vibration sense, as well as motor paralysis, but also have contralateral loss of pain and temperature sensation distal to the level of injury. Because the fibers of the lateral spinal thalamic tract cross at a different level, the pain and temperature loss may be found variably one or two segments above the lesion. Virtually all patients maintain bowel and bladder function and unilateral motor strength, and most become ambulatory.

The anterior cord syndrome results from hyperflexion injuries causing cord contusion by the protrusion of a bony fragment or herniated disk into the spinal canal or by laceration or thrombosis of the anterior spinal artery. This syndrome is characterized by paralysis and hypalgesia below the level of injury, with preservation of posterior column functions, including position, touch, and vibratory sensations. Suspicion for an anterior cord syndrome warrants prompt neurosurgical consultation because it is a potentially surgically correctable lesion. After surgical intervention, patients have variable degrees of recovery during the first 24 hours but little improvement thereafter.

Several less common spinal cord syndromes may result from direct injury to the cervicomedullary junction and upper cervical segments or from vertebral artery occlusion resulting from severe hyperextension (Fig. 36.27). The posteroiﬁererior cerebellar artery syndrome may produce dysphagia, dysphonia, hiccup, nausea, vomiting, dizziness or vertigo, and cerebellar ataxia. The Dejerine onion skin pattern of analgesia of the face is caused by damage to the spinal trigeminal tract. Horner’s syndrome results from damage to the cervical sympathetic chain and is characterized by ipsilateral ptosis, miosis, and anhidrosis. Injuries below the L2 level can result in an acute cauda equina syndrome, characterized by perineal or bilateral leg pain, bowel or bladder dysfunction, perianal anesthesia, diminished rectal sphincter tone, and lower extremity weakness.

The syndrome of SCIWORA is seen primarily in younger children but may occur in any age group. In fact, there is increasing evidence that SCIWORA has been underreported in adults. The mechanism is unclear but has been ascribed to the increased ligamentous elasticity seen in the young, leading to transient spinal column subluxation, stretching of the spinal cord, and vascular compromise. Patients often experience a brief episode of upper extremity weakness or paresthesias followed by neurologic deficits that appear hours to days later. The prognosis for patients with SCIWORA is variable, depending on the degree of neurologic impairment and rate of resolution.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of spinal injuries includes peripheral nerve injuries that may mimic sensory or motor deficits from a central lesion. For example, compression of the superficial peroneal nerve from a fibular fracture may result in a foot drop, but impingement of a lumbar spinal nerve root from a lumbar vertebral fracture could also result weakness in dorsiflexion. As noted, ligamentous injury in SCIWORA is also a consideration, especially if no fractures are found on imaging. Muscle contusions and strains around the neck, thorax, and lumbosacral regions would also be part of the differential diagnosis. Finally, a diagnosis of exclusion, conversion disorder can result in apparent

manifestations of sensory and motor deficits that may initially be confused and attributed to spinal injuries.

**DIAGNOSTIC TESTING**

**Radiographic Evaluation**

**Indications**

Emergency clinicians have historically taken a liberal approach to imaging the cervical spine in the setting of trauma because failure to recognize an SCI may result in devastating neurologic consequences. In an effort to standardize clinical practice and guide emergency clinicians to be more selective in radiographic imaging without jeopardizing patient care, two clinical decision rules have been developed. Use of selective but safe imaging modality may decrease overall health care costs, reduce radiation exposure, and decrease complications (e.g., aspiration and pressure trauma to skin) associated with the patients lying flat on a backboards with a rigid collar. The first rule to be developed, the National Emergency X-Radiography Utilization Study (NEXUS) Low-Risk Criteria (NLC), was based on a multicenter prospective observational study involving almost 35,000 trauma patients seen at 21 EDs in the United States. The decision instrument required patients to meet five criteria to be classified as having a low probability of injury: (1) no midline cervical tenderness; (2) no focal neurologic deficit; (3) normal alertness; (4) no intoxication; and (5) no painful, distracting injury. The decision rule identified all but 8 of

![Sensory dermatomes](image_url)
the 818 patients who had spinal injuries. Two of these patients had a clinically significant injury, only one of whom required surgical stabilization, and neither sustained a permanent neurologic injury. Sensitivity, specificity, and negative predictive value of the NLC were 99.6%, 12.9%, and 99.8%, respectively.

Owing to concerns about the low specificity of the NLC, the Canadian C-Spine Rule (CCR) was developed using 25 selected clinical predictor variables associated with spine injury. In 2003, the CCR was prospectively studied and compared with the NLC in nine Canadian tertiary care hospitals. Of 8283 patients, 162 were found to have clinically significant injuries, and the sensitivity, specificity, and negative predictive values of the CCR were, respectively, 99.4%, 45.1%, and 100%. The CCR is composed of the following three questions:

1. Are there any high-risk factors that mandate radiography?
2. Are there any low-risk factors that allow safe assessment of range of motion?
3. Is the patient able to rotate his or her neck actively 45 degrees to the left and right?

According to the CCR, patients with no high-risk factors, any low-risk factor, and the ability to rotate the neck do not require radiographic evaluation. High-risk factors include age older than 65 years, a dangerous mechanism of injury (eg, fall from a height >1 m, axial loading injury, high-speed MVC [>100 km/hr], rollover, ejection, motorized recreational vehicle or bicycle collision), or the presence of paresthesias. Low-risk factors include simple rear-end vehicle crashes, to a sitting position in the ED, ambulatory at any time, delayed onset of neck pain, and absence of midline neck tenderness. Although the NEXUS criteria are more widely used in the United States, there is controversy regarding which of the two rules to implement; a systematic review demonstrated better diagnostic accuracy for the CCR. There are methodologic differences in the respective study designs, such as different inclusion and exclusion criteria. Nonetheless, both rules have been well-validated and are sensitive, and the use of either rule decreases the number of unnecessary radiographs while rarely missing clinically significant injuries.
Cervical Plain Radiographs

Due to the widespread availability and superior test characteristics of CT in the United States, spinal plain radiographs are now rarely obtained, especially when CT is ordered to visualize a different body part. Furthermore, plain radiographs have been shown to be inadequate to visualize the entire cervical spine in up to 72% of cases, thus necessitating CT. However, plain radiographs are often used outside the United States, and there is increasing concern regarding cost and exposure to medical radiation from CT. When compared to plain radiographs, CT respectively confers a 10-to-14-fold increase in radiation exposure to the skin and thyroid.

Thus, in light of cost and radiation exposure, plain radiographs of the cervical spine may be preferentially obtained in patients who sustain a relatively minor mechanism of injury but fail the NLC and CCR criteria, and do not warrant CT of the head or other body parts. On plain radiographs, the C7-T1 vertebrae may be obscured in muscular or obese patients, as well as in patients with spinal lesions causing paralysis of the muscles that act to depress the shoulders. In this case, a swimmer’s view of the lower cervical vertebrae, or CT, is often needed. The cross-table lateral view of the cervical spine is the most helpful x-ray, but its inadequacy as the sole view is well documented. The diagnostic yield is significantly increased when the AP and odontoid views are included. The NLC has shown that a technically adequate three-view trauma series will fail to diagnose significant spinal injury in only 0.07% of patients with injuries and in only 0.008% of patients with unstable injuries. Note that once CT is performed, however, plain radiographs do not add any further clinically relevant information and should not be obtained.

Cross-Table Lateral View. The inspection of the lateral cervical spine film should be methodical and complete. It is helpful to remember the ABCs of interpreting the lateral film, where A stands for alignment, B for bony abnormalities, C for cartilage space assessment, and s for soft tissues.

To check alignment, two imaginary lines are drawn that connect the anterior and posterior margins of the vertebral bodies, the anterior and posterior contour lines. A third line, the spinolaminar line, connects the bases of the spinous processes extending to the posterior aspect of the foramen magnum (Fig. 36.28). All three lines should form a smooth, continuous lordotic curve, and any disruption of these lines suggests a bony or ligamentous injury. An exception to this rule is the pseudosubluxation of C2 and C3, which is commonly seen in infants and children. This phenomenon is attributed to immature muscular development and a hypermobile spine. Thus, if a high cervical injury is suspected in a child, the posterior cervical line, which connects the points bisecting the bases of the spinous processes of C1 and C3, should be used (Fig. 36.29). If the base of C2 lies more than 2 mm anterior or posterior to the posterior cervical line, an injury at that level should be suspected. On the lateral view, the predental space, which is the distance between the anterior aspect of the odontoid process and posterior aspect of the anterior ring of C1, should not exceed 3 mm in an adult or 5 mm in a child (Fig. 36.30). A widening of this space may indicate a Jefferson fracture of C1.

Subtle signs of cervical subluxations and dislocations can be identified through cartilage space assessment. A slight anterior or posterior widening of the intervertebral or interspinous space may be the only clue to an unstable dislocation.

Finally, the soft tissues of the retropharyngeal space should be assessed for prevertebral swelling and hemorrhage, often the only radiographic signs of spinal injury. The retropharyngeal space, measured from the anterior border of the body of C2 to the posterior wall of the pharynx, should not exceed 6 mm in children or adults. At the level of C3 and C4, this should not exceed 5 mm or should be less than half the width of the vertebral body at that level (see Fig. 36.30). Below the level of C4, the prevertebral soft tissue space is widened by the esophagus and cricopharyngeal muscle. The retrotracheal space, measured from the anterior border of the body of C6 to the posterior wall of the trachea, should not exceed 22 mm in adults or 14 mm in children younger than 15 years. In children younger than 2 years, the retropharyngeal space may normally appear widened during expiration; therefore, inspiratory films should be obtained. Air in the prevertebral space may indicate rupture of the esophagus or some portion of the respiratory tree, and anterior bulging of the prevertebral fat stripe is an excellent sign of an underlying bony or soft tissue injury.

Odontoid View. The open-mouth or closed-mouth view of the atlas and axis can be helpful in diagnosing Jefferson and odontoid fractures. Nonfusion of the odontoid in children and congenital anomalies of the odontoid in adults may mimic fractures.

Anteroposterior View. The AP spinal film completes the spinal series. Connecting imaginary dots placed at the base of each spinous process should form a straight line, and the laryngeal and tracheal air shadows should be midline. The regular outline of the lateral masses should be verified, and the pedicles viewed
end-on can be checked for fracture. Widening of the interpedicu-
lar distance compared with adjacent vertebrae suggests a burst
fracture (Fig. 36.31). Bulging of the mediastinal stripe may be
the only evidence of a thoracic vertebral body fracture, which may
cause hemorrhage that produces mediastinal widening on the
chest x-ray.

Flexion and Extension Views. Flexion-extension (F/E)
views are rarely indicated in the acute evaluation of a patient
presenting to the ED after acute trauma, but may be useful when
there is concern for ligamentous injury and magnetic resonance
imaging (MRI) is not available. F/E views should be obtained only
in patients who are alert and able to articulate the presence of
pain, numbness, or paresthesias, because such symptomatology
may indicate instability. The NEXUS investigators demonstrated
that 86 of 818 patients (10.5%) ultimately found to have cervical
injury underwent F/E testing. Although two patients had bony
injuries and four patients had subluxations demonstrated only on
F/E views, all six patients had other injuries apparent on routine
radiographs.

F/E views are also deemed inadequate for interpretation in
nearly one-third of studies.5 A more recent review of 1000 F-E
radiographs revealed that 80% of the films did not demonstrate
the C7-T1 junction or had less than a 30-degree range of motion.9
In the acute setting, F/E radiographs have been reported to have
unacceptably high false-positive and false-negative rates because
of concomitant muscle spasm. Delayed F/E views obtained 1 week
after injury may be helpful, but they have little value in the ED
when the CT scan is negative.10 Thus, we do not recommend
obtaining F/E radiographs in the ED unless there is concern for
ligamentous instability in an alert evaluable patient, and MRI is
not available. Such evaluation should occur in consultation with,
and images should be obtained under the supervision of, a spine
or trauma surgeon.

Advanced Imaging: Computed Tomography and
Magnetic Resonance

The CT scan is the technique of choice for the evaluation of acute
cervical spine trauma because of its superior test characteristics
and time efficiency in the radiology department when compared
to plain radiography. CT permits examination without moving
the patient from the supine position and is thus preferable in
terms of fracture stabilization, airway control, and other life
support measures. CT can also identify bony fragments, acute disk
herniation, foreign body, paraspinous hematoma, or extramedul-
lary hematoma. Thus, routine plain radiographs in many centers
are reserved for the alert patient with minor trauma. In addition
to those undergoing CT imaging of other body parts, CT may be
preferred when plain radiographs are difficult to interpret because
of abnormal anatomy, such as in older adults with degenerative
disease or the patient with rheumatoid arthritis. Additionally,
rotational and distraction injuries resulting in atlanto-occipital
dislocations may be missed on plain x-ray. For patients who have
a severe mechanism of injury, unless CT is not available, we
support the practice guidelines from the Eastern Association for
the Surgery of Trauma, which recommend that CT from the
occiput to T1 be used as the primary screening. Because fractures
in contiguous and noncontiguous vertebrae are fairly common,
CT scans should be obtained to visualize the entire cervical spine.

Fractures involving the transverse foramina or C1-C3 are
associated with vertebral artery dissection or thrombosis in
up 22% of cases, as well as basilar artery stroke. When such
fractures are identified, we recommend further study by magnetic
Although CT has a higher sensitivity than MRI to detect fractures and dislocations at the cranio cervical junction, as well as fractures of the posterior elements, MRI, with its superior resolution and lack of ionizing radiation, has the primary advantage of the ability to image nonosseous structures directly, including intramedullary and extramedullary spinal abnormalities that potentially cause neurologic deficit (Fig. 36.32). Its major impact has therefore been in demonstrating potentially surgically correctable lesions, including acute disk herniation, ligamentous injury, bony compression, epidural and subdural hemorrhages, and vertebral artery occlusion. MRI can identify three separate patterns of SCI, including acute cord hemorrhage, cord edema or
contusion, and mixed cord injury. Patients with cord edema or contusion show significant neurologic improvement, whereas those with cord hemorrhage (Fig. 36.33) fare far worse. MRI can also diagnose a developing intramedullary (posttraumatic) syrinx or subarachnoid cystic changes (Fig. 36.34). MRI is also the best diagnostic imaging modality for SCIWORA. Thus, a patient who demonstrates neurologic deficit or persistent neck pain suggesting ligamentous injury or an occult spine injury, should undergo an expedited MRI, regardless of a normal CT scan or plain radiograph (Fig. 36.35).

There are risks to performing an MRI, however, such as aspiration, secondary brain injury, and the difficulty of monitoring and resuscitation in the MRI suite. In addition, MRI cannot be used when MRI-incompatible life support, monitoring systems, pacemakers, cerebral aneurysm clips, and cervical traction devices are used, although MRI-compatible support systems exist. In the obtunded or unreliable patient, MRI may not be necessary to exclude unstable injuries if the CT scan is normal. A recent prospective study of the use of cervical spine CT in 402 obtunded patients reported a sensitivity of greater than 99%.14

**MANAGEMENT**

Spinal injury should be suspected in all trauma victims with an unknown or suggestive mechanism of injury associated with complaints of neck or back pain, evidence of significant head or facial trauma, spinal tenderness, signs of focal neurologic deficit, impaired consciousness, potentially distracting injuries, or unexplained hypotension (Fig. 36.36).

**Spinal Column Stabilization**

**Out-of-Hospital Care**

Prehospital personnel are well versed in the care of the patient with a potentially traumatized spine, and all emergency medical services (EMS) incorporate these principles. The traditional approach to immobilization requires the use of a backboard, rigid cervical collar, and supportive blocks on both sides of the head. In the past, a concerning mechanism of injury called for automatic and routine initiation of such spinal immobilization at the scene. However, it has been noted that many trauma patients are unnecessarily immobilized by EMS, and immobilization is not a benign intervention. For example, in addition to resulting in prolonged on-scene time and delayed transport to definitive care, the backboard can lead to pressure ulcers, increased pain, and decreased functional respiratory residual capacity. Also, the cervical collars can hide other injuries, such as lacerations and hematomas, and have even been found to result in worsening vertebral distraction injuries.15 There is also ample evidence that EMS providers can safely apply spinal assessment guidelines, such as NEXUS.

**Emergency Department**

Trauma victims are assessed as described in Chapter 33 while maintaining immobilization. If the patient’s spine can be clinically cleared by use of the NEXUS criteria or CCR, the immobilization device may be removed. If the trauma victim was wearing a helmet and the helmet was not removed in the field, the face mask, helmet, and any sports padding (eg, shoulder pads on hockey or football players) may be carefully removed while immobilization is maintained. Ideally, at least two or three providers should be present to perform the task of helmet removal. Once the helmet and shoulder pads have been removed, a rigid collar should be placed if the patient’s cervical spine cannot be cleared by use of the NEXUS criteria or CCR.

Patients with probable spinal injury who are conscious and cooperative should be immobilized until imaging has been performed. Patients who are uncooperative because of head injury, drug or alcohol intoxication, hypotension, or presence of multiple painful injuries require a deliberate approach, including the use of chemical and mechanical restraints. Suspected thoracic and lumbar spinal injuries are best managed by keeping the patient supine and immobile. The goal of stabilization in cervical spine trauma is to immobilize the neck and body because any movement may extend the initial injury. If the patient is not already immobilized on a backboard, the torso should be firmly anchored to the examining table by straps or rolled sheets. Sedation, drug-induced paralysis, and intubation may be required for patients who pose a danger to themselves because of excessive movement and whose injuries otherwise will likely require intubation. Paralysis and intubation are not used simply to control patient...
Spinal precautions should be maintained in patients with an altered sensorium until the presence of an injury can be excluded clinically or radiographically. Suctioning should be readily available to prevent aspiration. Vomiting patients should be placed on their side by logrolling while spinal alignment is maintained.

**Airway Management**

Cervical spine injuries often require early intubation as part of the resuscitation. Lesions above C3 may rapidly progress to respiratory paralysis, and the spread of edema from a lower injury may cause delayed phrenic nerve paralysis, as well as ascension of the neurologic injury above the level of C3. Cervical injuries may be associated with airway obstruction from retropharyngeal hemorrhage or edema or maxillofacial trauma.

Airway management of the trauma patient, including those with suspected spine injury, is discussed in Chapter 1.

**Spinal Shock**

Spinal shock is characterized by the temporary loss of neurologic function and autonomic tone below the level of an acute spinal cord lesion. Patients usually exhibit flaccid paralysis with loss of sensation, deep tendon reflexes, and urinary retention, along with bradycardia, hypotension, hypothermia, and intestinal ileus. Recovery from spinal shock, which may last from less than 24 hours to more than 2 weeks, is heralded by the return of the bulbocavernosus reflex.

Neurogenic hypotension, caused by loss of vasomotor tone and lack of reflex tachycardia, is a diagnosis of exclusion in the trauma victim. It should not be considered the cause of hypotension.
Approach in such patients and may result in fluid overload. Thus, when there prevention and treatment. Fluid resuscitation is often ineffective severe hypotension (systolic blood pressure hypoperfusion and secondary spinal cord ischemia, prolonged total loss of neurologic function. Because hypotension can lead to hypotension and may not require fluid resuscitation or will respond to modest NEPA, 70 mm Hg), seen in 20% to 30% of cases, usually occurs with high cervical injuries associated with total or near-total loss of neurologic function. Because hypotension can lead to hypoperfusion and secondary spinal cord ischemia, prolonged severe hypotension (systolic blood pressure < 70 mm Hg) should be prevented and treated. Fluid resuscitation is often ineffectivem in such patients and may result in fluid overload. Thus, when there is persistent hypotension despite fluids, we recommend vasoressor support with norepinephrine to be started at 0.05 µg/kg/min and titrated upward to a maximum dose of 1 µg/kg/min to achieve an MAP of 85 mm Hg.

Pharmacologic Treatment for Incomplete Cord Injury

Delayed biochemical damage contributes to ongoing tissue loss and worsening neurologic function in SCI. Thus, numerous neuroprotective and neuroregenerative treatment strategies, including pharmacologic treatment, hypothermia, and decompression,16-18 have been investigated in laboratory animal studies and human clinical trials. Substantial media attention was prompted by case reports of athletes, such as the Buffalo Bills tight end Kevin Everett, who underwent therapeutic hypothermia and was subsequently able to walk just 3 months after his treatment. Since 2010, there has been one prospective case series of 20 patients,17 two retrospective case series,18,19 and one case report.19 In all these studies, the patients had surgical decompression in addition to the hypothermia treatment (32°C–34°C [89.6°F–93.2°F]) for 6 to 48 hours and, although there appeared to be some association of hypothermia with improvement in the American Spinal Injury Association Impairment Scale, this cannot be considered evidence in support of the use of therapeutic hypothermia for acute spinal cord injury. Reported complications from hypothermia induction include pneumonia, thrombocytopenia, and atrial fibrillation. The Miami Project to Cure Paralysis is a phase 1 study currently being conducted at the University of Miami and should be able to help delineate the risks and benefits better, as well as the duration of hypothermia.20 At this time, hypothermia should be considered experimental. Methylprednisolone, once widely recommended for use on the basis of extremely weak evidence, has been found to have no benefit and is likely, on balance, to be harmful. It is no longer recommended or used for acute spinal cord injury.

Associated Injuries

Cardiopulmonary

Although cardiopulmonary deterioration in a trauma victim is usually the result of hemorrhagic shock or direct injury to the heart or lungs, pulmonary edema may also occur in response to brain injury and SCI. Spinal cord trauma stimulates an intense sympathetic discharge with two subsequent effects. First, pulmonary capillary endothelial cells are disrupted, leading to the pulmonary capillary leak syndrome, in which pulmonary edema occurs in the presence of normal pulmonary artery pressures (<18 mm Hg). Second, marked increases in afterload may lead to pulmonary edema associated with high pulmonary artery pressures (>18 mm Hg) from ventricular dysfunction. Excessive fluid resuscitation can also contribute to pulmonary edema. Later in the recovery period, many SCI patients suffer from alternating episodes of low and high blood pressure, often with labile heart rates, termed autonomic dysreflexia.21 The treatment for this is primarily supportive by addressing causative factors, such as bladder distention, pain, and hydration status.

Gastrointestinal and Genitourinary

If SCI renders the abdominal examination unreliable, an abdomin CT scan or ultrasound is often necessary. In the acute stages of SCI, the gastrointestinal tract and bladder become atonic. Thus, a nasogastric tube should be placed to prevent gastric distention and a Foley catheter inserted to prevent bladder distention and monitor fluid output. Because gastrointestinal bleeding from

**Fig. 36.36.** Approach to a patient with suspected cervical spine injury. AP, Anteroposterior; CT, computed tomography.
stress ulcers occurs in 2% to 20% of spinal trauma patients, ulcer prophylaxis with histamine H2 receptor antagonists or proton pump inhibitors should be initiated.

Skin

Denervated skin is extremely susceptible to pressure necrosis, and sores can develop in less than 1 hour on unpadded spinal carts. Therefore, backboards should be removed as soon as possible. Padding pressure areas with sheepskin or foam can help minimize decubitus ulcers.

Definitive Treatment and Prognosis

The role of prompt surgical intervention in the management of spinal injuries is currently limited to relieving spinal cord impingement caused by foreign bodies, herniated disks, bony fracture fragments, or epidural hematoma. Surgery may be necessary later to stabilize severe bony injuries or reduce spinal displacements. The timing of surgical intervention is controversial because there are no well-designed studies that have determined whether early (<12 hours) versus late decompression is beneficial.

Once almost uniformly fatal, major spinal injury caused death from pulmonary complications or sepsis from skin necrosis or urinary infection. The advent of antibiotic therapy made long-term survival not only possible but also expected. Today, patients with SCIs are best managed at a regional spine injury center, where a team of neurosurgeons, orthopedic surgeons, psychologists, and physical therapists can initiate rehabilitation. Specialized SCI treatment centers offer patients a chance to return to a productive life within the limits of their disability. With the exception of patients with high cervical lesions (above C3), most patients attain sufficient independence to live outside of high-level care environments.

DISPOSITION

Cervical Soft Tissue Injuries

Patients with cervical soft tissue injuries of the spine who have only mild to moderate discomfort without neurologic impairment or abnormal radiographic findings (WAD class 1 or 2) are best managed as outpatients. Discharge instructions should include educating the patient that pain often increases over the first 24 to 48 hours but that the symptoms will begin to dissipate thereafter. We recommend treatment with analgesics, such as acetaminophen, 650 to 1000 mg/dose, up to qid. Although analgesic doses of a nonsteroidal antiinflammatory drug, such as ibuprofen, 400 to 600 mg/dose, is also reasonable, there is ample evidence that acetaminophen, which has fewer adverse effects on the gastrointestinal and renal systems, is equally effective, and there is no indication for antiinflammatory treatment. Additionally, we do not recommend medications with purported muscle relaxant properties, such as cyclobenzaprine, because they have not been found to provide additional benefit and have an adverse side effect profile (principal anticholinergic effects and drowsiness). Finally, referral for follow-up with a primary care physician is indicated because up to 50% of patients experiencing neck pain after trauma will continue to have symptoms at 1 year. This is more likely in patients with WAD class 3 but can occur in patients with class 2 and rarely class 1. Box 36.1 lists the prognostic indicators of poor functional recovery in patients with a WAD.

Minor Fractures

Most patients with spinal fractures require hospitalization. Patients with isolated cervical vertebral body compression or spinous process fractures may be managed as outpatients if there is no evidence of neurologic impairment or associated ligamentous instability, and the degree of patient distress is not severe. Appropriate follow-up should be arranged for all patients because even minor spinal injuries may be associated with prolonged disability from chronic pain.

For patients with minor wedge fractures (<10% compression of the anterior vertebral body height) who do not have an associated ileus or neurologic deficit, outpatient management may be possible. However, most wedge fractures of the thoracic and lumbar spines are usually best managed in the hospital for several reasons. First, patients with these injuries usually have marked discomfort, often requiring parenteral opioid analgesia. Second, significant force is generally required to fracture thoracic or lumbar vertebrae, and associated intrathoracic or abdominal injuries are common. Third, lower thoracic and lumbar fractures are associated with prolonged and occasionally delayed gastrointestinal ileus, requiring continuous nasogastric suction. Finally, older adults who have vertebral fractures and only minor associated injuries may require admission to facilitate assessment of fall risks and expedite rehabilitation.

BOX 36.1

Prognostic Indicators of Poor Functional Recovery Following Whiplash-Associated Disorders

FACTORS WITH CONSISTENT EVIDENCE FOR BEING PROGNOSTIC INDICATORS FOR POOR RECOVERY

- Initial pain levels > 5.5/10
- Initial disability levels: NDI > 29%
- Symptoms of posttraumatic stress
- Negative expectations of recovery
- High pain catastrophizing
- Cold hyperalgesia

FACTORS WITH CONSISTENT EVIDENCE OF NOT BEING PROGNOSTIC INDICATORS

- Accident-related features (eg, collision awareness, position in vehicle, speed of accident)
- Findings on imaging
- Motor dysfunction

FACTORS WITH INCONSISTENT EVIDENCE

- Older age
- Female gender
- Neck range of movement
- Compensation-related factors

NDI, Neurological Disability Index.
The anterior cord syndrome, characterized by paralysis and hypalgesia below the level of injury, with preservation of position, touch, and vibration, results from hyperflexion injuries causing cord contusion, by the protrusion of a bony fragment or herniated disk into the spinal canal, or by laceration or thrombosis of the anterior spinal artery. Suspicion for an anterior cord syndrome warrants prompt neurosurgical consultation because it is a potentially surgically correctable lesion.

In the awake, evaluable trauma patient, the NEXUS or CCR decision rules may be used to determine the need for radiographic imaging.

In the awake, evaluable trauma patient, unless the patient has a very minor trauma mechanism (or CT is not available), CT is preferred over plain radiography, especially if CT is being performed on other body parts.

Neurogenic hypotension, caused by loss of vasomotor tone and lack of reflex tachycardia, is a diagnosis of exclusion in the trauma victim. It should not be considered the cause of hypotension unless the patient is flaccid and areflexic, reflex tachycardia and peripheral vasoconstriction are absent and, most importantly, the possibilities of coexisting hemorrhagic shock, cardiac tamponade, or tension pneumothorax have been eliminated.

Because neurogenic hypotension can lead to hypoperfusion and secondary spinal cord ischemia, prolonged, severe hypotension (systolic blood pressure < 70 mm Hg) should be prevented and treated. When there is persistent hypotension despite fluid resuscitation, we recommend vasopressor support with norepinephrine to be started at 0.05 µg/kg/min and titrated upward to a maximum dose of 1 µg/kg/min to achieve an MAP of 85 mm Hg.

Methylprednisolone or any other steroid is not beneficial in the treatment of acute spinal cord injury and should not be used.

Emergency department management of SCI includes care to prevent pressure ulcers, bladder distention, and gastric distention.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

is the first step regardless of the traumatic hypotensive cause. The possibilities of coexisting hemorrhagic shock, cardiac tamponade, tension pneumothorax, or other life-threatening injuries should first be addressed. The absence of vasomotor activity in patients with neurogenic hypotension may mask the usual presentation of these life-threatening injuries. In this case, the lack of flaccidity and presence of reflexes argues for a nonneurogenic cause for the hypotension.
Neck

CHAPTER 37

PRINCIPLES

Background

Trauma to the neck comprises a spectrum of injuries ranging from incidental to life threatening and can include airway occlusion, hemorrhagic shock, or acute neurologic/vascular injury. Airway compromise can rapidly ensue, challenging even the most experienced clinician. Stable-appearing patients may harbor insidious injuries associated with high morbidity and mortality if not recognized and treated in a timely manner.

Neck trauma is divided into three major mechanisms: blunt, penetrating, and strangulation/hanging. These mechanisms can be further categorized anatomically into injuries of the laryngotracheal, pharyngoesophageal, and vascular systems. Each has unique features and will be discussed separately.

Anatomy

The neck is a complex, closed anatomic area, dense with vital structures and invested with fascia, creating several compartments. Because of this, vascular injury with hemorrhage may be contained by fascial planes and neighboring structures, leading to occult, life-threatening anatomic distortion, making evaluation and airway management extremely difficult. Anatomically, the neck is divided into anterior and posterior triangles. The anterior triangle is densely packed with vital structures including neurovascular and aerodigestive tracts. It is bordered anteriorly by the midline, posteriorly by the sternocleidomastoid muscle, and superiorly by the lower edge of the mandible. The posterior triangle is bounded by the sternocleidomastoid muscle anteriorly, the clavicle inferiorly, and the anterior border of the trapezius muscle posteriorly. Excluding spinal trauma, injury to this region often has a more favorable prognosis because of the relative paucity of vital structures.

Historically, for evaluation of penetrating neck trauma, the neck has been divided into Zones I, II, and III (Fig. 37.1), and the location of an injury within one of these zones guided the management approach. It is useful to maintain an understanding of the neck zones for the purposes of communication with other providers. Many current algorithms use zone driven protocols for diagnostics and management. As technology has continued to improve, multi-detector computed tomography angiography (MDCTA) has become the gold standard for the initial screening of most symptomatic, stable penetrating neck injuries. Use of MDCTA has also demonstrated that penetrating neck injury can span multiple zones not evident from the surface wound, making the surface zone location less relevant, and allowing for more rapid and accurate nonsurgical evaluation than in the past.1,2 Some practitioners and institutions have abandoned the zone system of nomenclature, but others have continued to use it. Either approach (traditional zone based or modern no-zone) have been shown to be safe and effective. The decision to use one system versus the other will be provider and institution specific, driven by clinical preference and consideration of available resources.3 Zone I (base of neck) extends superiorly from the sternal notch and clavicles to the cricoid cartilage. It includes the thoracic outlet below the cricoid cartilage. Injury to this region can affect both neck and mediastinal structures. Zone II (midneck) is the area between the cricoid cartilage and the angle of the mandible. Zone II injuries are therapeutically distinct because they lie in the most exposed region of the neck, making them accessible to direct surgical intervention with access to both proximal and distal vascular control. Zone III (upper neck) extends from the angle of the mandible to the base of the skull. As with Zone I injuries, proximal and distal vascular control in this region is difficult to achieve (Box 37.1).

Two fascial layers, the superficial fascia and the deep cervical fascia, cover neck structures. The superficial fascia covers the platysma muscle and is located just below the skin. The deep cervical fascia is divided into three parts: the investing layer surrounds the neck and splits to encase the sternocleidomastoid and trapezius muscles; the pretracheal layer adheres to the cricoid and thyroid cartilages and travels caudally deep to the sternum to insert on the anterior pericardium; and the prevertebral layer envelopes the cervical prevertebral muscles and extends to form the axillary sheath, which covers the subclavian artery. The pretracheal fascia is clinically important because of its connection from the neck to the anterior mediastinum. Missed aerodigestive injuries can result in mediastinitis because of this anatomic continuity. The carotid sheath is made of portions from all three divisions of the deep cervical fascia. The platysma muscle, sandwiched between the superficial and deep cervical fascia, envelopes the anterolateral neck. If the platysma muscle is violated, injury to deep structures should be suspected, and platysmal violation is used to separate superficial, unimportant injuries from those warranting evaluation of the deep structures at risk.

Pathophysiology

Penetrating injuries are most often gunshot wounds (GSWs) or stab wounds (SWs). GSWs are further divided into high-velocity and low-velocity injuries. High-velocity missiles (military-style weapons and hunting rifles) easily penetrate soft tissue and bone. Their pathway is generally predictable, causing both direct injury along the path of travel and remote injury via blast effect. Blast or cavitation effect pertains to moderate or high velocity missiles and is caused by the immediate release of kinetic energy as the bullet enters the tissue. Cavitation can lead to extensive soft tissue damage beyond that caused directly by the bullet’s path. Low-velocity injuries result from missiles that travel at significantly slower speed and tend to produce erratic pathways, with injuries often demonstrating no direct relationship to the location of the entrance or exit wounds.4 Lower-velocity projectiles cause less severe clinical injury than high velocity projectiles, but injuries can be life-threatening, nevertheless. In the past decade, the overall mortality rate for penetrating neck trauma has been reported to be around 5% in civilian victims, comparable to the rate seen in war casualties.1,5
Diagnostic testing in the emergency department (ED) will apply primarily to the stable patient. Patients with neck injury should be thought of in terms of whether or not they will require emergent or urgent surgical intervention in the operating room (OR). They can generally be divided into four categories: (1) hemodynamically unstable, (2) hard signs of injury with or without hemodynamic instability, (3) hemodynamically stable with soft signs of injury, and (4) asymptomatic. Patients in either...
of the first two categories will most likely go to the OR emergently or urgently. If a patient displays hard signs of injury (defined later), but remains hemodynamically stable, they may go directly to the OR or undergo evaluation and imaging and then be taken to the OR for surgical exploration. Despite variability in the definition of hemodynamic instability, any blood pressure (BP) lower than 90 mm Hg should be considered unstable. 

Diagnostic testing is indicated for stable patients exhibiting soft signs of injury and, sometimes, for those who present asymptptomatically. Airway stabilization should always be of primary concern, and this is discussed in detail in the Management section.

Patients with penetrating neck injury are evaluated for the presence of soft or hard signs of aerodigestive or neurovascular injury during the primary and secondary survey (Box 37.2). Definitions of hard signs of injury vary. Hard signs equate with the need for immediate surgical or endovascular intervention. Not all patients with hard signs are hemodynamically unstable, yet even stable patients will likely need expeditious surgical intervention in the OR. Hard signs are indicative of injury to either the aerodigestive or neurovascular structures. Hard signs of aerodigestive injury include air bubbling from the wound, substantial subcutaneous emphysema, or airway compromise. Hard signs of neurovascular injury include significant hematoma (whether pulsatile or not) significant hemoptysis, active bleeding, shock unresponsive to fluid, decreased or absent radial pulse, vascular bruit or thrill, or cerebral ischemia. Institution specific factors (availability of imaging and surgery subspecialties, for example) determine which variation of these hard signs selects patients for immediate transport to an OR. Despite hard signs being an indication for expedited transfer to the OR, there are times when some pre-OR diagnostic imaging might be helpful in the otherwise stable patient. An example of this would be head and neck computed tomography angiography (CTA) to identify whether unilateral neurological deficit in a MVC victim is caused by injury to the carotid artery or to the brain.

Soft signs of injury (see Box 37.2) necessitate further diagnostic evaluation but are less likely than hard signs to require surgical exploration. Ancillary testing is dependent on several parameters, including location of injury, specific signs and symptoms (soft signs), resource availability, and institution-specific protocols. The most common study obtained is CTA. Other diagnostic tests for particular presentations can include plain radiographs of the neck or chest (primarily to locate the missile or fragments), contrast esophagography, flexible or rigid endoscopy, laryngoscopy or flexible nasopharyngoscopy, duplex ultrasound, magnetic resonance angiography (MRA) or conventional angiography. Indications for these ancillary, diagnostic tests will be addressed under the specific anatomic injury further in this chapter.

Researchers historically remained divided as to whether patients lacking both hard and soft signs required further diagnostic evaluation. Two large prospective studies of patients with penetrating neck wounds found that physical examination and symptoms were reliable in determining which stable patients needed vascular or esophageal diagnostic studies. Currently, management varies in these asymptomatic patients from serial examination and observation to diagnostic studies, such as CTA. The age of the patient, availability of both imaging studies and personnel, ability to perform serial assessment of the wound, and patient’s social situation need to be considered in making this decision.

**MANAGEMENT**

The evaluation of penetrating neck trauma depends on the anatomic zone of injury, clinical presentation, and hemodynamic stability. Early management is based on whether the patient requires immediate surgery, extensive evaluation for injury to the deep structures of the neck (airway, digestive, vascular, neurological), serial evaluation and observation, or discharge after ED evaluation.

Whenever feasible, patients with neck injury should be transported to a trauma center. Despite a stable initial appearance, airway compromise can ensue rapidly, and intervention is essential at the first sign of airway threat, ideally before respiratory symptoms develop. Necessary stabilization procedures should be initiated during transport to the ED when possible rather than at the scene to avoid delays in definitive care.

**Airway**

Airway management is the highest initial priority in any patient with neck trauma. Bag mask ventilation may be hazardous because it may force air into injured tissue planes, resulting in massive subcutaneous emphysema and subsequent airway distortion or, rarely, air embolus. Aside from obvious injury to the airway or overt airway distress or compromise, the clinician should look for signs of impending or future compromise of the airway. These can include neck hematoma, upper airway hemorrhage or hematoma, voice change or significant subcutaneous emphysema, any of which can progress to distort or occlude the airway. These are all considered indications for early airway stabilization (see also Chapter 1).

Although the ideal technique to secure a definitive airway for patients with neck trauma has been heavily debated, orotracheal intubation with rapid sequence intubation (RSI) has been shown to be safe and effective and should be considered the first-line airway technique in the emergent situation, preferably using a video laryngoscope. Video laryngoscopy confers advantage through improved glottic views and less need for neck manipulation. 

If the cervical spine must remain immobilized during orotracheal intubation, an assistant should hold inline stabilization of the head and neck. Relative contraindications to RSI include significant anatomical disruption of the face or neck, massive hematemesis, or concern that RSI will not succeed and

### BOX 37.2

“Soft” and “Hard” Signs of Penetrating Neck Trauma

**SOFT SIGNS**
- Minor hemoptysis
- Hematemesis
- Dysphonia, dysphagia
- Subcutaneous or mediastinal air
- Nonexpanding hematoma
- Oropharyngeal bleeding
- Neurological findings
- Proximity wound

**HARD SIGNS**
- Rapidly expanding/pulsatile hematoma
- Massive hemoptysis
- Air bubbling from wound
- Severe hemorrhage
- Shock not responding to fluids
- Decreased or absent radial pulse
- Vascular bruit or thrill
- Stridor/hoarseness or airway compromise
- Cerebral ischemia
- +/- Massive subcutaneous emphysema
the patient will not be successfully oxygenated using a bag and mask, laryngeal mask airway, or other device. If time and resources allow, fiberoptic laryngoscopy may be preferable; however, this procedure requires skill with endoscopy and is not feasible when there is significant bleeding. Institution-appropriate rescue and surgical airway equipment should be available if standard orotracheal intubation fails.

Blind nasotracheal intubation has been associated with serious complications, including false passage, and is contraindicated in patients with penetrating neck trauma. If endotracheal intubation is not possible, cricothyrotomy may be required (see Chapter 1).

Breathing

When the airway has been stabilized, breathing assessment is standard, with consideration of the associated risk of hemothorax or pneumothorax, seen primarily with penetrating zone I injuries.

Circulation

Open wounds should be covered and sufficient compression applied to control bleeding and prevent air embolus without occluding the airway or blood flow to the brain. Wounds with active bleeding or blood clots should not be probed because massive hemorrhage can ensue. Ideally, bleeding is controlled by direct pressure. Blind clamping of active bleeding sites should be avoided because of the high concentration of neurovascular structures in the neck. Intravenous (IV) access is best placed on the uninjured side, avoiding the ipsilateral neck or upper extremity.

Occasionally, exsanguination from penetrating trauma in the ED is imminent. In those cases, direct pressure on the wound is first-line treatment, followed by insertion of fingers into the wound or packing the wound to facilitate compression if direct pressure alone is unsuccessful. Occasionally, these measures will fail, particularly in zone III wounds. Insertion of a 16- or 18-French ballooned catheter into the wound with inflation of the balloon to tamponade bleeding during transport to the operating suite may be helpful.

Cervical Spine

The placement of a cervical collar is unnecessary in most cases of penetrating neck trauma without neurological deficits. One large series found an overall incidence of 0.4% unstable cervical spine injuries in patients who had sustained penetrating neck injury. Cervical collars can obscure neck pathology and preclude adequate examination. In any patient with blunt neck or multisystem trauma, and in particular if altered, there should be greater concern for occult or overt cervical spine injury.

Thoracotomy

In patients presenting to the ED with cardiopulmonary resuscitation (CPR) in progress, the indication for resuscitative thoracotomy is CPR for less than 15 minutes with penetrating neck trauma or less than 10 minutes of CPR with any blunt trauma. Arrest in the ED, or profound, refractory shock are also indications in either scenario. Mortality from resuscitative thoracotomy for any type of blunt trauma resulting in CPR is exceedingly high with survival rates cited in the 1% to 2% range.

Venous/Arterial Air Embolism

Venous air embolism (VAE) causes profound shock or cardiopulmonary arrest unresponsive to fluids or thoracotomy. If VAE is suspected, placing the patient in a head-down, left lateral decubitus position will cause intra-cardiac air to accumulate in the apex of the right ventricle. If shock persists, aspiration of air from the apex of the right ventricle either by use of an ultrasound-guided pericardiocentesis needle or under direct visualization after ED thoracotomy can be lifesaving. Neurologic sequelae or any otherwise unexplained stroke-like syndrome should prompt consideration of arterial air embolism. Controversy surrounds the best patient position when considering the diagnosis of arterial air embolus, and there are no large trials to provide a definitive answer. Because arterial emboli can lead to cerebral edema, we recommend placing the patient in a neutral position after cardiac aspiration is completed and vital signs restored.

Nasogastric Tubes

Placement of a nasogastric tube (NGT) is relatively contraindicated in patients with penetrating neck injury and should be avoided if at all possible. Exceptions are when placement is required to decompress a stomach distended by positive pressure ventilation to permit improved respiratory support. Ideally, placement is deferred until after intubation, because it may no longer be deemed necessary, and, if necessary, can be inserted gently and with endoscopic guidance, if available. The NGT aspirate may be helpful because bloody aspiration implies visceral injury.

PHARYNGOESOPHAGEAL TRAUMA

PRINCIPLES

Epidemiology

Esophageal injuries are rare, and most are due to penetrating trauma and involve the cervical segment. Injury from blunt trauma is typically associated with hyperextension or cervical spine fractures.

Pathophysiology

Early diagnosis of esophageal injury is crucial because spillage of orogastric contents with bacterial contamination can lead to florid inflammation, abscess, and mediastinitis. Delayed diagnosis of esophageal injuries contributes to their mortality rate of up to 20%.

CLINICAL FEATURES

In penetrating trauma, air leaking out through the wound site is the most compelling indicator of an underlying esophageal or airway injury. Otherwise, there are no pathognomonic signs of esophageal injury. Soft signs of injury include hematemesis, odynophagia, dysphagia, subcutaneous emphysema, and blood in the saliva or NGT aspirate (see earlier discussion of placement of NGT). Other associated findings include dyspnea, hoarseness, stridor, cough, pain and tenderness in the neck, and resistance to passive neck movement. Physical examination is unreliable in diagnosing esophageal injury, and a normal examination does not exclude aerodigestive injury. However, absence of any symptoms or soft signs, coupled with a normal physical examination makes esophageal injury extremely unlikely, and serial evaluation can replace any other further diagnostic testing in this setting, depending on institution-specific protocols.

DIAGNOSTIC TESTING

Timely diagnosis is associated with decreased morbidity and mortality, with poorer outcomes found in patients treated beyond
24 hours from the time of injury. Plain films of the neck and chest alone are inadequate but may suggest esophageal perforation if pneumomediastinum, hydrothorax, or retropharyngeal air is present.

Contrast esophagography, which requires the patient’s cooperation, has a sensitivity of 90% for esophageal injuries. Typically, water-soluble contrast (eg, diatrizoate meglumine and diatrizoate sodium [Gastrografin]) is used. Barium has greater sensitivity, but has more danger associated with extravasation. A thin barium swallow can be used to increase sensitivity if the Gastrografin swallow is negative. Flexible endoscopy follows a negative contrast esophagography study. This combination of tests has a sensitivity approaching 100%.

Sole reliance on CTA, without oral contrast, for diagnosis of esophageal injuries is currently not supported by the literature. Although computed tomography (CT) scan can be useful to look at the wound track or trajectory of a bullet to determine if a proximity wound is likely, its sensitivity is variable and is as low as 50%. Extravasation of contrast is rarely seen, and non-oral contrast CT depends on visualization of indirect signs, such as paraesophageal air or fluid, esophageal wall thickening, or edema. In patients in whom the pre-test suspicion is low, CT demonstration of a wound track distant from the esophagus may be sufficient. In higher risk injuries, addition of a contrast swallowing study is recommended. If available, thin (5 mm) section contrast CT esophagography has test characteristics comparable to standard barium swallow and is an alternative option. Additionally, evaluation for vascular or airway injury is recommended prior to repair of the esophageal damage; half of patients with penetrating esophageal injuries will have a concurrent laryngotracheal injury.

**MANAGEMENT**

When esophageal injury is suspected, broad-spectrum antibiotics with anaerobic coverage (eg, piperacillin and tazobactam IV 3,375 grams every 6 hours) should be administered, and the patient should receive nothing by mouth. Preoperative placement of an NGT under endoscopic guidance may reduce the spillage of gastric contents into the wound. Any uncontained perforation of the esophagus requires prompt surgery, whereas small contained perforations may be candidates for observation and reimaging.

Esophageal stents are gaining popularity for certain nontraumatic perforations and may have applications in trauma as well. Isolated pharyngeal injury can be managed nonoperatively in the majority of cases.

**LARYNGOTRACHEAL TRAUMA**

**PRINCIPLES**

Laryngotracheal injuries account for less than 1% of all trauma injuries, but a substantial proportion of immediate mortality. Most blunt laryngotracheal injuries result from direct blunt force sustained in MVCs, often without a shoulder restraint, in which the extended neck strikes the steering wheel or dashboard and the larynx is compressed between the fixed object and the cervical spine. Other mechanisms leading to laryngotracheal injuries include clothesline injuries, improperly fitting shoulder harnesses, near hanging, assaults, athletic events, attempted strangulation, and iatrogenic wounds.

The cricoid cartilage is the only complete solid ring in the larynx. Fractures of the cricoid cartilage can lead to death through acute airway obstruction and are the most serious laryngeal injuries. Calcification of the laryngeal cartilages begins during the teenage years. The degree of airway obstruction after blunt trauma to the larynx is inversely related to the degree of cartilage calcification, putting children at highest risk of respiratory compromise after injury. These injuries can lead to long-term sequelae, including recurrent pneumonia, dysphonia, voice change, dysphagia, laryngeal stenosis, and chronic pain, and risk and severity of sequelae increases with delayed or missed diagnosis.

**CLINICAL FEATURES**

Not all surgically significant laryngotracheal injuries will manifest clinically at the time of initial evaluation in the ED, particularly in the case of blunt trauma. Bubbling or air leakage from a neck wound signals injury to the respiratory tract and is considered a hard sign of laryngotracheal injury. Massive subcutaneous air and crepitus over the larynx (caused by laryngeal fracture) represent laryngotracheal injury until proven otherwise. A clothesline mechanism of injury makes laryngotracheal injury more likely than other blunt mechanisms. Other clinical features of laryngotracheal injury include dysphonia, aphonia, dyspnea, stridor, hemoptysis, subcutaneous emphysema, laryngeal crepitus, neck tenderness or pain over the larynx, a visible neck wound, or loss of anatomic landmarks secondary to hematoma. However, each individual finding occurs in fewer than 50% of cases. Pain with tongue movement or rotation of the head implies injury to the hyoid bone or laryngeal cartilage. Patients with laryngotracheal injury may be unable to tolerate lying flat. Soft tissue surrounding the injury can serve as a makeshift air conduit, and minimize respiratory distress initially, even with complete laryngotracheal separation. Because blunt laryngotracheal injuries are often seen in association with multisystem trauma, they can be easily overlooked; however, they portend a higher mortality and often mandate early airway management.

**DIAGNOSTIC TESTING**

Plain radiographs, if performed, should be evaluated for extraluminal air, edema, foreign bodies, and fracture or disruption of the cartilaginous laryngeal structures. Laryngoscopy or flexible nasopharyngoscopy allows direct evaluation of laryngeal integrity. With appropriate local anesthesia, laryngoscopy is well tolerated by most patients, even those in cervical spine immobilization collars. Anesthesia and preparation for an emergent airway should precede laryngoscopy in the semi-stable patient, because instrumentation-related irritation and cough can cause sudden laryngospasm or airway disruption. Rigid endoscopy is useful to evaluate injury distal to the larynx but is performed in the OR under general anesthesia.

With a sensitivity approaching 100%, CT scanning is the imaging modality of choice, providing detailed information about laryngeal integrity and the surrounding region. When soft tissue anterior neck injury is suspected, 1-mm cuts of the larynx should be obtained and multiplanar reconstructions performed to optimize the study. CT is useful for assessing airway diameter and vocal cord integrity, as well as for detecting fractures of the hyoid bone, disrupted laryngeal or tracheal cartilages, significant exolaryngeal or endolaryngeal hematoma, and dislocations of the cricothyroid or cricoarytenoid joints. It is less useful for the detection of mucosal perforations, degloving injuries of the cartilage with denuded mucosa, certain types of minor laryngotracheal separation, particularly when there are poorly calcified pediatric cartilaginous structures. Typically, injuries missed by CT scan are unlikely to require surgical management.

Widespread access to ultrasound has led to an increase in its use for trauma patients. Whereas some advocate ultrasound to detect blunt laryngotracheal injuries such as laryngotracheal separation, larger studies are needed before we can recommend this modality.
Airway compromise in patients with laryngotracheal trauma can be immediate or delayed. Because delayed airway occlusion can be rapid and life-threatening, these patients require close monitoring. When laryngotracheal injury is suspected, early laryngoscopy is indicated to identify injuries and determine the need to secure the airway. When emergent airway management is required, the approach should be individualized, based on the suspected injuries, the patient’s overall status, and the ability to tolerate examination by laryngoscopy under local anesthesia, without or without sedation. If available, an awake, fiberoptic-guided oral intubation is likely the best route. If this is not feasible given the status of the patient, or availability of equipment and operator, and anatomy is reasonably preserved, “awake” intubation using a video laryngoscope (see Chapter 1) is a good alternative. If an awake technique is not feasible, the best approach often is a single attempt at orotracheal intubation under a “double set-up,” using RSI, but with preparations in place to move immediately to a surgical airway (cricothyroidotomy or tracheostomy) if intubation is not successful on the first attempt. The airway lumen may be compromised by edema or hematoma, so endotracheal tubes of varying sizes, including several sizes smaller than would normally be used for the patient, should be prepared for use. A tube one size smaller than what is typically used is a good first selection.

Most patients can be intubated in a standard fashion, but the laryngoscope (unless a flexible scope is used) is not capable of visualizing the airway below the vocal cords, so the tube must be placed very gently and guided down the airway with the least contact or friction. This will minimize the possibility of completing a partial laryngotracheal separation or creating a false passage. Depending on the location and extent of the injury, tracheostomy may be preferred over cricothyrotomy because of the potential for the latter to further damage an injured larynx. When the airway is managed in the OR, tracheostomy is preferred. In the ED, management is often more time pressured, and cricotthyroidotomy, provided the anatomy is preserved, usually is preferred, because it is faster and easier to perform. In cases with a large neck wound, intubation can be performed through the wound, provided the trachea can be visualized.

Complete laryngotracheal separation is often fatal. If complete laryngotracheal separation is present with distal retraction of the trachea, orotracheal intubation is unlikely to be successful, but may be tried, as described earlier, using a small (cuffed) tube and gentle technique, if flexible endoscopy is not available. If a surgical approach is chosen, after vertical incision in the neck, tracheal hooks can be used to recover the distal end of the trachea, and tracheostomy performed at the fourth or fifth tracheal ring to avoid the larynx. Blind nasotracheal intubation or use of positive pressure supraglottic ventilation (eg, bag/mask or laryngeal mask airway) is contraindicated in these injuries. The risk of decompensation with intubation, the condition of the patient, and the available resources/consultants must all be weighed carefully.

For the majority of injuries, a period of hospitalization for observation is required. Patients with no identifiable injury, beyond laryngeal tenderness, but who had a significant mechanism of injury (significant energy transfer to the larynx) can be observed for 12 hours in the ED or an ED observation unit and discharged home if no additional symptoms or signs develop, voice and swallowing are normal, and discomfort is minimal and abating. These patients should have their first 6 hours of observation in the ED to ensure stability before transfer to the observation unit for the remainder of their visit. Most small mucosal injuries, hematomas, and nondisplaced fractures can be managed conservatively with analgesia, humidified air, elevation of the head of the bed, antibiotics, steroids, antireflux medications, vocal rest, and a clear diet. Unstable patients or those with higher-grade injuries require surgical repair.

### Vascular Trauma

#### Principles

The great vessels of concern in the neck include the carotid, subclavian, and vertebral arteries and the internal and external jugular veins. Morbidity and mortality occurs via exsanguination, hematoma expansion with subsequent airway distortion and compromise, direct vessel injury leading to vascular occlusion, or embolization of a foreign body (eg, shotgun pellet to brain or heart). Delayed-onset, evolving, central neurologic deficits in a patient with any neck trauma should prompt assessment of the carotid arteries for dissection.

### Penetrating Injury

Arterial injuries, including extravasation, pseudoaneurysm, occlusion, dissection, and arteriovenous fistula formation, occur in 25% of all penetrating neck wounds, and 37% of deep penetrating neck wounds have some vascular injury. Vessels are injured directly in most cases, although the blast effect can cause indirect intimal injury. Mortality rates range from 10% to 50%.

### Blunt Injury

Blunt cerebrovascular injuries (BCVIs) are rare, occurring in less than 2% of blunt trauma victims. Mortality rates for blunt cervical vascular injuries range to 60%. The internal carotid artery is the most frequently injured artery, followed by the vertebral artery. Blunt trauma to the cervical vessels can result in a spectrum of arterial injuries, including intimal tears, thrombosis, dissection, and pseudoaneurysm. Embolization can then occur from a thrombus that develops at the injury site. The most common mechanism for blunt internal carotid artery injury is sudden, forceful hyperextension and lateral rotation of the neck. This mechanism can cause stretching of the carotid artery over the transverse processes of the upper cervical vertebrae, resulting in intimal injury. Other mechanisms responsible for this type of injury include direct blunt force to the side of the neck, intraoral trauma, and basilar skull fractures involving the petrous or sphenoid portions of the carotid canal. Blunt carotid artery injuries most often result from MVCs but have also been reported after fights, athletic events, seat belt injuries, and strangulations. Vertebrobasilar arterial injuries may follow relatively minor trauma, such as chiropractic neck manipulation, but most commonly occur in association with fractures of the spinal column.

#### Clinical Features

### Penetrating Injury

Hard signs of arterial injury include active hemorrhage, hematoma that is expanding or is pulsatile, new bruit, fluid-unresponsive shock, massive hematemesis or hemothysis, or appropriate focal neurologic deficits. Over 80% of patients with penetrating neck trauma and hard signs of vascular neck or aerodigestive injury (air leaking through injury site or significant subcutaneous emphysema) will have vascular or aerodigestive injuries identified. By contrast, fewer than 20% of patients with soft signs of vascular injury (non-pulsatile, nonexpanding hematomas, minor
hemoptysis) or aerodigestive injury (eg, dysphonia, dysphagia, any subcutaneous emphysema) will have a significant injury to either of these systems confirmed. For patients with neither hard nor soft signs, the likelihood of significant injury approaches zero, even when there is a wound in proximity to a vital structure, attesting to the value of risk-stratification of penetrating neck trauma patients based on the presence of physical examination findings.\(^{36} \) The decision to obtain diagnostic studies or to observe the asymptomatic patient with isolated neck trauma, particularly one with a wound proximal to a vascular structure, is guided by institutional policy and practice, and depends on the availability of imaging, ability of the provider to assess the patient, and potential for ongoing observation both in the ED and following discharge at home.

**Blunt Trauma**

Half the patients with dissection from blunt trauma are neurologically asymptomatic. When symptomatic, carotid injuries cause either transient or fixed contralateral sensory or motor deficits, aphasia, dysphasia, and Horner syndrome, whereas vertebral injuries can cause ataxia, vertigo, emesis, and visual field deficits.\(^{37} \) Neurological symptoms are often delayed. Most symptoms develop 10 to 72 hours post-injury with a median of 12.5 hours.\(^{38,39} \) Up to one-third of patients may not develop deficits for more than 24 hours.\(^{39} \) Delay in onset of neurological sequelae of weeks to years has been reported. Any unexplained focal neurologic abnormality after blunt or penetrating trauma involving the head or neck should prompt consideration of vascular injuries. Similarly, patients with arterial epistaxis are at risk and should be evaluated.

Because of the potential for delay in symptom onset and catastrophic outcome, screening of asymptomatic patients with associated injuries has become standard. Cervical spine injury, mandible fracture, basilar skull fracture, high injury severity score, and low ED Glasgow Coma Score (GCS; below 6 or 8) have been found independently predictive of a BCVI in an otherwise asymptomatic patient.\(^{40} \) Cervical spine injury is the strongest risk factor, with an associated BCVI in up to 45% of isolated cervical spine fractures.\(^{41,42} \) Screening criteria differ slightly between authors, centers, and organizations, and those from the Western and Eastern Trauma Associations are listed in Table 37.2.\(^{44,45} \) Unfortunately, screening guidelines, such as the Eastern Association for the Surgery of Trauma (EAST) screening criteria, typically miss about 20% of injured patients.\(^{46} \) Expanding these criteria to include all cervical spine fractures and select patients with complex facial fractures or mandible fractures may increase sensitivity of clinical criteria for BCVI screening.\(^{41,46,47} \) At a minimum, screening should be performed in patients with cervical spine fractures or injuries in C1 to C3, transverse foramen fracture at any level, low GCS, LeFort II or III fracture, basilar skull fracture involving the petrous bone, and patients with an appropriate mechanism of hyperextension or hyperflexion with rotation and significant injuries to the head, face, and neck.

Seat-belt signs, or visible abrasions on the neck, are often a concern for physicians evaluating these injuries. Firstly, a “seat-belt sign” should be differentiated from a large hematoma, which is of greater concern. Secondly, several authors have included “seat-belt sign” in the list of variables evaluated, without proving them contributory in multivariate analysis. In two recent studies focused specifically on the impact of the seat-belt sign, no vascular injury was found in a single patient with an isolated seat-belt sign without signs of vascular injury or criteria for asymptomatic screening.\(^{48,49} \)

In children, the rate of BCVI is lower, likely around 0.4%.\(^ {50} \) Evaluation and management mirrors that of the adult patient.

**DIAGNOSTIC TESTING**

**Penetrating Trauma**

Traditionally, for cases without overt hard signs of vascular injury, the less accessible zones I and III were evaluated radiographically, whereas the more surgically accessible zone II injuries underwent operative exploration. However, many patients with penetrating mechanisms will have injuries outside of the zone cutaneously affected.

CTA has a 90% to 100% sensitivity and 99% to 100% specificity for vascular injury in penetrating neck trauma.\(^ {39,51,52} \) Both direct CT signs (wall irregularity, contrast extravasation, lack of vascular enhancement, and caliber changes) and indirect signs (sheath hematoma, bone or bullet fragments <5 mm from a major vessel) are used in diagnosis.\(^3 \) CTA may help surgical planning in the stable patient with loss of the carotid pulse lacking neurologic deficits or a new bruit.\(^1 \) However, it is primarily useful in evaluating patients with soft signs of injury, as patients with hard signs will typically need operative management.

**Blunt Trauma**

Historically, conventional arteriography (digital subtraction angiography [DSA]) has been used extensively to detect vascular injury in patients with both blunt and penetrating injuries. DSA should include the intracranial portion of the carotid artery with zone III injuries or suspected blunt cervical trauma. Zone I injuries should include the aortic arch with its branches.
Sensitivity and specificity are nearly 100% and complication rates are less than 2%.55 For blunt trauma, CTA has become standard, and few patients with a negative CTA develop adverse neurological outcomes.54,55 However, its sensitivity is still substantially lower when compared to DSA (51% to 89%).54,56,58 Nearly 80% of the lesions missed by CTA are grade 2 or higher.56 False positives are frequently reported as well. Therefore, for patients in whom the pre-test probability is high and a CTA is therefore unexpectedly negative, further testing (eg, DSA) should be undertaken unless clinical evaluation suggests the contrary.

Other Radiographic Options
Although not indicated in most cases of suspected vascular injury, plain films can occasionally be useful. Anteroposterior and lateral neck films can help determine a bullet trajectory. Chest radiographs allow evaluation of the mediastinum and identification of hemothorax or pneumothorax.

Duplex ultrasonography has shown variable performance in the evaluation of cervical vascular injury in patients with both penetrating and blunt trauma, risking misses of zone I and zone III injuries. For penetrating injury, carotid duplex Doppler has higher sensitivity, but for symptomatic dissection patients without obvious evidence of stroke, sensitivity of ultrasound is inadequate.

MRA has additional distinct disadvantages that include remote location in many centers, the contraindication of metallic foreign bodies (bullet fragments), length, cost, availability, and the inability to directly visualize the neck during the procedure for expanding hematoma. Reports of sensitivity are variable, but it is likely equivalent to that of CTA for carotid injury and possibly inferior for vertebral dissections.

MANAGEMENT
The goals of management are twofold: repair of acute life-threatening hemorrhage and prevention of stroke. Mortality in patients suffering a stroke following a vascular injury is significantly higher than those who do not (34% vs. 7%).60

Penetrating Injury
The ideal management strategy for injuries of the vascular system resulting from penetrating trauma has not been determined, although surgical repair is common. In cases with brisk hemorrhage or those in whom reperfusion might convert an ischemic infarction to a hemorrhagic infarction in patients with profound neurologic deficit, some prefer selected ligation over repair. Vertebral artery injuries are often more amenable to endovascular repair.59

Blunt Injury
Treatment options for blunt arterial injuries depend in part on the mechanism, type of injury, and location of the lesion. Injuries are typically graded as 1 (intimal irregularity with <25% narrowing), 2 (dissection or intramural hematoma with ≥25% narrowing), 3 (pseudoaneurysm), 4 (occlusion), and 5 (transsection with extravasation). Treatment modalities include anticoagulation, surgery, and observation. Anticoagulation is widely used for dissection, although there is no convincing evidence that it clearly improves outcome. For anticoagulation, antiplatelet agents and heparin have comparable injury healing rates, and no difference was noted between outcomes in patients given heparin, aspirin, or a combination of aspirin and clopidogrel.61 Because of high complication rates in trauma patients, treatment should be initiated with appropriate consultation with vascular surgery or neurosurgery. Surgical treatment includes ligation, resection, thrombectomy, endovascular stent placement, and, in the case of severe hemorrhage in a small vessel with collateral circulation, transarterial embolization. Endovascular stent therapy is less invasive than surgery and considerably easier to perform in less surgically accessible regions. In non-randomized studies, endovascular stents were typically used in higher-grade lesions, with comparable outcomes to medical management. Stent patients are generally managed with a week of heparin, followed by 6 months of aspirin or a combination of aspirin and clopidogrel.61 For low-grade lesions, particularly dissection, long-term occlusion outcomes are better with anticoagulation and antiplatelet therapy compared to stenting.62 Appropriate treatment reduces stroke rate from about one-quarter of patients to 3.9%.60 Repeat imaging in 7 to 10 days assesses recannulation, as well as pseudoaneurysm formation. Enlarging or symptomatic pseudoaneurysms merit treatment, particularly in patients with question-able follow-up.

NERVOUS SYSTEM, GLANDULAR, AND RETROPHARYNGEAL INJURIES
The brachial plexus, peripheral nerve roots, cervical sympathetic chain, the spinal cord, and cranial nerves VII, IX, X, XI, and XII are vulnerable to trauma. Neurologic deficit can also result from vascular injury with subsequent cerebral ischemia. Complete cord injury can result in spinal (neurogenic) shock with paraplegia, bradycardia, and hypotension. Brown-Séquard syndrome (hemi-section of the spinal cord) arises with ipsilateral hemiplegia and contralateral sensory deficit. Cervical spine fractures and cord injuries are most commonly found in GSWs (1.35% and 0.94%, respectively), followed by direct blunt trauma. Either injury is rare from SWs (0.12% and 0.11%).61 Brachial plexus, spinal root, and peripheral nerve injuries have been reported after neck trauma and can result in both sensory and motor deficits. Phrenic nerve injury may compromise spontaneous respiration by causing ipsilateral diaphragmatic paralysis. Hoarseness can result from direct laryngeal trauma but also from injury to the recurrent laryngeal nerve, which branches off the vagus nerve (cranial nerve X), leading to vocal cord paralysis. Sixty percent of patients with transection of the cervical trachea will experience recurrent laryngeal nerve damage.65 Other less common injuries have been reported in association with neck trauma with variable signs and symptoms. Thoracic duct injuries are less likely to be apparent initially and are frequently diagnosed intraoperatively or after chylothorax develops. Glandular wounds, including those of the thyroid, parathyroid, and salivary glands, are reported rarely. Thyroid rupture or hemorrhage can occur, with an expanding hematoma causing increasing respiratory distress over the 24 hours following an injury.64 Isolated retropharyngeal hematomas, typically from a whiplash mechanism, are also extremely rare but can result in life-threatening airway compromise.67

NEAR HANGING AND STRANGULATION PRINCIPLES
The terms hanging and strangulation are often used interchangeably, with hanging being a subset of strangulation. Judicial hanging victims classically fell at least the height of their body, whereas most suicides fall little to no distance and are termed non-judicial. Complete hanging refers to the victim who is freely suspended, while incomplete hanging refers to the partial suspension of the
part II

section one

General Concepts and System Injuries

Victim’s body with some part still in contact with the ground. Typical hanging refers to the ligature knot being midline directly under the occiput. Atypical hanging refers to all other knot placements. The maximal force is applied immediately opposite to the placement of the knot; therefore, typical hanging portends highest risk of arterial occlusion. Near-hanging is a common term referring to survivors of an attempted hanging.

Manual strangulation and ligature strangulation refer to external compression of the neck, usually by hands or ligature, but independent of the weight of the victim. Postural strangulation, generally seen in the younger pediatric population, refers to death sustained by the victim’s body weight compressing the anterior neck against a firm object.

Judicial hanging involving an adequate fall distance results in forceful distraction of the head from the neck and body, and this leads to high cervical fractures, such as the classic hangman’s fracture (fracture through both pedicles of C2), complete cord transection, and death. Non-judicial hangings frequently occur at less than 2.7 meters, usually inadequate to injure the cervical spine, except in the elderly population.

In essentially all types of non-judicial strangulation, ligature or external force causes venous congestion with stasis of cerebral blood flow leading to unconsciousness. Once the person is limp, the ligature or external force can tighten further, leading to complete arterial occlusion and ultimately to brain injury or death. Vagal reflexes resulting from pressure on the carotid body may contribute to fatal dysrhythmias, as may increased sympathetic tone from pericarotid sinus pressure. Compression of the airway does not play as significant a role.

Survivors of hanging can suffer sequelae in other systems; hypoxic-ischemic brain injury is the driving factor in the high mortality and neurologic morbidity. Pulmonary edema can occur from several mechanisms: neurogenic pulmonary edema from centrally mediated, massive sympathetic discharge; postobstructive from relief of the marked negative intrapleural pressure generated by forceful inspiratory effort against an extrathoracic obstruction; and cardiogenic pulmonary edema, which is increasingly recognized as a result of hanging-associated takotsubo cardiomyopathy.

Clinical Features

External trauma may or may not be evident. Ligature marks, fingernail scratches, abrasions, and contusions are variably present on the external neck as well. Tardieu spots are highly correlated with asphyxial deaths; these petechial hemorrhages are seen in the approximately half of all non-judicial hanging deaths.70

Three petechial hemorrhages are seen in the anterior neck as well.

Fingernail scratches, abrasions, and contusions are variably present on the external neck as well.

Ligature marks, fingernail scratches, abrasions, and contusions are variably present on the external neck as well.

Tardieu spots are highly correlated with asphyxial deaths; these petechial hemorrhages are seen in the anterior neck as well.

Thyroid cartilage fractures and/or hyoid bone fractures are seen in approximately half of all non-judicial hanging deaths.70

More commonly seen with manual strangulation, cricoid cartilage fractures are rarely reported in suicidal hangings, and there are few survivors.72 These are significant less common (=7%) in survivors of near-hanging.

Vascular injury leading to delayed neurologic sequelae after near-hanging is rare. Carotid injury occurs in only a tiny fraction of near-hangings. In a study of 56 survivors of manual strangulation, 16% of whom lost consciousness and 63% of whom had a neck hematoma, no laryngeal, hyoid, or vascular damage was identified on magnetic resonance imaging (MRI).

Diagnostic Testing

Suggested radiographic evaluation for hanging or strangulation with suspected injury includes head CT and neck CTA.

Management

Techniques for managing the airway are as for other blunt neck trauma. The addition of positive end-expiratory pressure is often necessary, especially when pulmonary edema or acute respiratory distress syndrome (ARDS) develops. Full resuscitative effort is warranted even in the unconscious patient, because full recovery is possible. The altered or comatose patient should be assumed to have cerebral edema with elevated intracranial pressure, and cerebral resuscitation measures should be initiated.

Definitive studies providing guidelines for the management of hypoxic brain injury specifically related to near-hanging or strangulation injuries are lacking. Case series indicate a potential role for induced mild hypothermia in comatose survivors of strangulation.74,75 One study demonstrated a 43% rate of survival to discharge and 6% return of neurological function in hanging patients treated with hypothermia after arrest.76 Case reports have suggested use of thrombolysis for carotid injury related stroke in survivors of near-hanging, although this is not widely studied.77 However, the data are not sufficient at this point to recommend either for clinical practice.

Disposition

Most patients with penetrating or blunt neck trauma warrant admission to the hospital, especially when their condition justifies further diagnostic studies, surgery, or intensive care. All patients with platysma muscle violation should be admitted to the surgical service or the observation unit for ongoing observation, regardless of their stability. Careful observation should be maintained for patients with blunt neck injury; because they can manifest delayed signs and symptoms of visceral or vascular injury with serious consequences. Some patients may require transfer to trauma centers, if required services are not available at the initial receiving facility. Pediatric trauma victims fare better when transferred directly to a trauma center.

Key Concepts

• Neck trauma results from three major mechanisms: blunt injury, penetrating injury, or near hanging or strangulation. Platysma violation defines a penetrating injury.

• The external neck is divided into zones I, II, and III. Zone designation has anatomic, diagnostic, and management implications in penetrating trauma, but use of computed tomography angiography (CTA) has greatly simplified the approach to the evaluation. Many injuries involve more than one zone.

• Zone I and III respectively encompass the thoracic inlet and base of skull, and penetrating injuries to these regions risk more occult vascular injury.

• Airway stabilization is the first priority in neck trauma. In most instances, flexible endoscopy is preferred, if possible, but orotracheal rapid sequence intubation (RSI), using a double set-up is also a valid approach. A surgical airway option should be available.

• Cervical spine injury in penetrating neck trauma without neurological deficits is extremely rare.

• Esophageal injuries are uncommon but represent the most frequently missed neck injury. Delays in diagnosis carry an extremely high mortality.

• Hard signs of vascular injury following penetrating trauma include rapidly expanding or pulsatile hematoma, massive hemoptyis, severe

• Airway stabilization is the first priority in neck trauma. In most instances, flexible endoscopy is preferred, if possible, but orotracheal rapid sequence intubation (RSI), using a double set-up is also a valid approach. A surgical airway option should be available.

• Cervical spine injury in penetrating neck trauma without neurological deficits is extremely rare.

• Esophageal injuries are uncommon but represent the most frequently missed neck injury. Delays in diagnosis carry an extremely high mortality.

• Hard signs of vascular injury following penetrating trauma include rapidly expanding or pulsatile hematoma, massive hemoptyis, severe
hemorrhage, shock not responding to fluids, decreased or absent pulse, vascular bruit or thrill, respiratory distress, and/or cerebral ischemia. Hard signs of aerodigestive injury include air bubbling from wound or extensive subcutaneous emphysema. Typically, patients with hard signs require prompt surgical intervention.

- Blunt vascular injuries are often asymptomatic but can present with immediate or delayed neurological sequelae. Cerebral ischemia, aphasia, dysphagia, Horner syndrome, ataxia, vertigo, visual field defects, and emesis should prompt consideration of anterior or posterior circulation vascular injury.
- Seat-belt signs should be differentiated from neck hematomas (the latter being of greater concern). The literature does not support an isolated cervical seat-belt sign as a sign of vascular injury.
- CTA is more than 90% sensitive for the detection of vascular injury with penetrating neck trauma but less sensitive for identifying vascular injury in blunt trauma. Digital subtraction angiography (DSA) is indicated for patients with high pre-test probability of injury but a normal CTA.
- A leading cause of in-hospital death following near-hanging or strangulation are pulmonary complications, including pulmonary edema, which has three primary etiologies: postobstructive, neurogenic, and cardiac.

CHAPTER 37: QUESTIONS & ANSWERS

37.1. The presence of which of the following signs after penetrating neck trauma would indicate a likely benefit from surgical intervention?
A. Decreased or absent radial pulse
B. Small degree of hemothorax
C. Horner syndrome
D. Muffled voice
E. Stable hematoma

**Answer:** A. “Hard” signs of penetrating neck trauma are the presence of an expanding hematoma, severe active bleeding, shock not responding to fluids, decreased/absent radial pulse, vascular bruit/thrill, cerebral ischemia, and airway obstruction. Most patients with hard signs benefit from surgical intervention.

37.2. Which of the following statements regarding airway management after penetrating neck trauma is true?
A. Awake fiberoptic intubation is the first-line technique.
B. Bag-valve-mask ventilation should be high tidal volume, low rate.
C. Cervical spine immobilization is typically unnecessary.
D. Nasotracheal intubation position is relatively contraindicated in neck trauma.
E. Preintubation nasogastric tube (NGT) placement may be lifesaving.

**Answer:** C. Unless there is concomitant blunt injury or evidence of spinal cord injury, cervical immobilization is not needed. Classic oral intubation after rapid sequence intubation (RSI) is the technique of choice and is successful in almost all cases. Although rarely a first line choice, nasotracheal intubation has been used successfully in these trauma patients. Gentle bag-valve-mask technique with low pressures is indicated to avoid venous air embolism (VAE) and subcutaneous emphysema. NGT placement, if done at all, should be gentle and placed after intubation.

37.3. A 21-year-old male presents after a small-caliber gunshot wound (GSW) to the left neck. He is hypotensive, hypoxic, and lethargic, but physical examination is remarkable only for a small zone I penetrating wound on the left side, with no gross swelling or crepitus. Oral intubation and rapid crystalloid infusion fail to improve his blood pressure (BP) or oxygen saturation. A portable chest radiograph is negative. While still in the emergency department (ED), his systolic blood pressure (SBP) drops to the 30s and is fluid unresponsive. What is the most appropriate next step in management?
A. Computed tomography (CT) scan of the neck and chest
B. Dopamine infusion at 20 µg/kg/min
C. Emergent blood transfusion
D. Emergent surgical consultation for neck exploration
E. Resuscitative thoracotomy

**Answer:** E. After penetrating trauma, the presence of profound shock or cardiopulmonary arrest unresponsive to fluids should prompt the initiation of a resuscitative ED thoracotomy. During that procedure, options C and D should already be in place, but this patient is too unstable to be transported to CT scan and while in extremis, should remain in the ED for the thoracotomy. Another consideration if the thoracotomy does not yield hemodynamic improvement is that of a venous air embolus.
CHAPTER 38

Thoracic Trauma

Ali S. Raja

Many causes of early deaths (within the first 30 to 180 minutes) resulting from thoracic trauma are preventable and include tension pneumothorax, cardiac tamponade, airway obstruction, and uncontrolled hemorrhage.

Approximately 75% of patients with thoracic trauma require only simple tube thoracostomy and volume resuscitation, and the initial care and disposition of these patients is usually performed by emergency clinicians. Care of severe thoracic trauma is multidisciplinary in nature, involving trauma surgeons, cardiothoracic surgeons, and intensivists. Improved understanding of underlying physiologic mechanisms, newer imaging modalities, minimally invasive approaches, and pharmacologic therapies have contributed to decreasing morbidity and mortality in patients with thoracic injuries.

Injury location and type dictates both assessment and management. This chapter is organized into sections for chest wall, pulmonary, tracheobronchial, diaphragmatic, cardiovascular, and esophageal injuries.

CHEST WALL INJURY

RIB FRACTURE

Principles

Background and Importance

The susceptibility to rib fracture increases with age. These injuries can be exquisitely painful, but their importance lies not in the fracture itself, which generally is self-limiting and will heal, but rather associated complications, particularly pneumothorax, hemothorax, pulmonary contusions, and post-traumatic pneumonia. Rib fractures in children are discussed in Chapter 165.

Anatomy and Physiology

An intact chest wall, protected by its rib cage, is necessary for normal ventilation. Outward expansion of the thorax by the respiratory muscles with descent of the diaphragm creates negative intrathoracic pressure. This allows passive air entry into the lungs during inspiration. Chest trauma, particularly blunt trauma, can severely disturb the physiology of respiration. Fortunately, most individuals have substantial respiratory reserve and can tolerate significant chest wall injury with adequate support.

Flail chest results when three or more adjacent ribs are fractured at two points, allowing a free segment of the chest wall to move in paradoxical motion (Fig. 38.1), with the flail segment moving inward with inspiration and outward with expiration. It can also occur with costochondral separation or vertical sternal fracture in combination with rib fractures. Underlying pulmonary contusion is considered to be the major cause of respiratory insufficiency with flail chest, and it is therefore one of the most serious chest wall injuries (Fig. 38.2). In addition, flail chest can be associated with a variety of other injuries, including hemopneumothorax, liver or spleen lacerations, and mediastinal injury.

Pathophysiology

Ribs usually break at the point of impact or at the posterior angle or posterolateral area, which is structurally the weakest area. The 4th through 9th ribs are most commonly involved. Ribs 1 to 3 are short and relatively protected, and ribs 9 to 12 are longer and more mobile at the anterior end. This confers the relative resistance to fracture of the “high” and “low” ribs. Fractures occur more easily in older adults than younger adults or in children, due to the progressive inelasticity of the chest wall that develops through aging.

The true danger of rib fracture involves not the rib itself but the potential for penetrating injury to the pleura, lung, liver, or spleen. Fractures of ribs 9 to 11 are also associated with intra-abdominal injury. Right-sided rib fractures are associated with hepatic injury and left-sided rib fractures with splenic injury. Injury severity is indicated by the number of rib fractures. The presence of two or more rib fractures at any level is associated with a higher incidence of internal injuries than with a single, isolated fracture. Patients older than 65 years old with multiple rib fractures have a greater incidence of pneumonia and a higher mortality compared to their younger counterparts.

Clinical Features

Rib fracture is often a clinical diagnosis, with severe point tenderness, bony crepitus, ecchymosis, and muscle spasm over the rib being the most common findings. Also, bimanual compression of the thoracic cage remote from the site of injury (barrel compression test) usually produces pain at the site of fracture. Injury to the parenchyma may be detected by assessing the respiratory rate, oxymyoglobin saturation, respiratory effort, effectiveness of ventilation, and pulmonary sounds.

Flail chest is characterized by paradoxical motion of a portion of the chest wall during inspiration, and is usually obvious on physical examination. Unless the patient is unconscious, there will be severe pain, splinting, tenderness, and crepitus. Paradoxical chest wall motion is a product of negative intrathoracic pressure, and is obscured if the patient has been intubated and is receiving positive-pressure ventilation. For such patients, the diagnosis is usually evident on examination of the integrity of the chest wall (compression, crepitus).

Differential Diagnoses

Patients with suspected rib fracture have always sustained trauma, thus focusing the evaluation. Patients with significant, potentially multisystem trauma require a thorough trauma evaluation (see Chapter 33). Rib fracture, costochondral separation, and rib contusion may present in similar fashion, and it is not critical to identify a single, isolated rib fracture. Patients with multiple suspected fractures are at higher risk for intrathoracic injury and also for later decompensation and complications. Important diagnoses to consider include chest wall or clavicle fracture (especially sternal fracture), pulmonary injuries (pulmonary contusion/
chronic obstructive pulmonary disease (COPD) is a concern. A plain chest radiograph will identify only about 50% of single-rib fractures; its greatest value is in identifying or excluding significant intrathoracic and mediastinal injuries. Rib series and expiratory, oblique, and cone-down views should not be used routinely. If additional imaging is required beyond a standard upright posteroanterior and lateral chest x-ray, a computed tomography (CT) scan should be obtained (Fig. 38.3). A CT scan is not indicated to confirm suspected isolated rib fracture, but it will identify multiple-level fractures and associated pulmonary injury, such as pneumothorax or hemothorax, with much greater accuracy than additional chest x-ray views.

In an attempt to limit unnecessary use of diagnostic ionizing radiation, the National Emergency X-Radiography Utilization Study (NEXUS) group derived and validated a decision instrument to guide the use of chest CT in patients with blunt trauma.1 The NEXUS-Chest CT derivation and validation studies, performed at eight trauma centers in the United States, enrolled 11,477 patients. In the validation phase, their decision instrument had a sensitivity of 95.4%, a negative predictive value of 93.9%, and a specificity of 25.5% for all thoracic injuries. The results were even more impressive for major clinical injuries, with both sensitivity and negative predictive value approaching 100% (99.2% and 99.8%, respectively). We recommend that CT scan not be obtained for patients sustaining blunt trauma who do not meet any of the seven NEXUS-Chest CT criteria (Box 38.1).2

**Diagnostic Testing**

Many patients with relatively minor thoracic trauma are evaluated and managed exclusively based on physical findings, and they do not require imaging. When the injury is significant enough to raise concern for underlying pulmonary injury, imaging is required. Because rib fractures are managed expectantly, imaging should be reserved for patients in whom multiple rib fractures, underlying pulmonary injury, or comorbid pulmonary status (eg, laceration, pneumothorax, or hemothorax), tracheobronchial injury, diaphragmatic injury, cardiovascular injury (cardiac contusion or aortic injury), or esophageal injury. This broad differential diagnosis holds true for most patients with thoracic trauma, given the close proximity of the organs involved and the similar mechanisms behind most of the injuries in this chapter.

Management

Respiratory decompensation is the primary indication for endotracheal intubation and mechanical ventilation for patients with multiple rib fractures. Obvious problems, such as hemothorax or severe pain, should be corrected before intubation and ventilation are presumed necessary. In the awake and cooperative patient, noninvasive continuous positive airway pressure (CPAP) by mask may obviate the need for intubation. In general, the most conservative methods for maintaining adequate oxygenation and preventing complications should be used. Adequate analgesia is of paramount importance in patient recovery and may contribute to the return of normal respiratory mechanics.

Treatment of acute rib fractures is based on adequate pain relief and the maintenance of pulmonary function. Outdated management techniques involving stabilization of the flail segment by positioning the person with the injured side down or placing a sandbag on the affected segments have been discredited. These interventions actually inhibit expansion of the chest and produce increased atelectasis of the injured lung. Instead, oxygen should be administered, cardiac and oximetry monitors applied, and the patient observed for signs of an associated injury, such as tension pneumothorax.

Otherwise well patients with single rib fractures are managed with opioid and non-opioid analgesics. These injuries can be severely painful, and regular opioid medication, particularly at bedtime, is usually necessary for up to a week. Thereafter, simple analgesia with acetaminophen or a nonsteroidal anti-inflammatory analgesic generally will suffice. Continuing daily activities and deep breathing should be stressed to ensure ventilation and prevent atelectasis. It is helpful to advise patients to wait 30 to 45 minutes after taking their pain medications before performing deep breathing exercises, ideally with an incentive spirometer.

The greater the number of fractured ribs is, the higher the mortality and morbidity rates. Hospitalization should be considered for patients with three or more fractured ribs, despite the lack of other identified injuries, to receive pulmonary therapy, repeated evaluation, and appropriate effective analgesia. Elderly patients with six or more fractured ribs should be treated in intensive care units owing to high morbidity and mortality.

Multiple rib fractures in trauma patients are associated with significant morbidity and mortality. Intercostal nerve blocks with a long-acting anesthetic, such as bupivacaine with epinephrine, may relieve symptoms up to 12 hours. Other alternatives for hospitalized patients include patient-controlled analgesia, parenteral opioids, and thoracic epidural analgesia.

For flail segments, consultation with a trauma or thoracic surgeon is essential to plan for surgical intervention. Early operative internal fixation of the flail segment results in a speedier recovery, decreased complications, and better cosmetic and functional results, and it is cost-effective. Indications for open fixation for flail chest include patients who are unable to be weaned from the ventilator secondary to the mechanics of flail chest, persistent pain, severe chest wall instability, and a progressive decline in pulmonary function.

The patient with flail chest should be treated in the emergency department (ED) as if pulmonary contusion exists regardless of whether mechanical ventilation is used.

Disposition

Most rib fractures heal uneventfully within 3 to 6 weeks, and patients should expect a gradual decrease in their discomfort during this period. However, in addition to the complications of hemothorax, atelectasis, pulmonary contusion, and pneumonia, rib fractures can result in post-traumatic neuroma, empyema, nonunion, or costochondral separation. These rare complications are painful and heal slowly (if at all). Patients with blunt trauma and multiple rib fractures should be observed for 12 to 24 hours to ensure that occult vascular or intrapulmonary injuries are not present and then considered for discharge, with the full understanding that the rib fractures themselves will require a prolonged recovery period and close follow-up.

The outcome of flail chest is a function of associated injuries. Because many different physiologic mechanisms have been implicated in flail chest, there is no consensus about hospital treatment. The cornerstones of therapy include pulmonary physiotherapy, effective analgesia, selective use of endotracheal intubation and mechanical ventilation, and close observation for respiratory compromise.

STERNAL FRACTURE

Principles

Background and Importance

Sternal fractures and dislocations are caused primarily by anterior blunt chest trauma (eg, motor vehicle collisions [MVCS] or bicycle accidents when the chest strikes the steering wheel or handlebars). Risk factors for sternal fracture from blunt trauma include types of vehicular passenger restraint systems and patient age. Restrained passengers are more likely than unrestrained passengers to sustain sternal fracture, likely related to the central location of the shoulder portion of the restraint. Cardiac complications, such as myocardial contusion, occur rarely, and there is no association between sternal fracture and aortic rupture. Although sternal fractures may occur in the context of major blunt chest trauma, the presence of a sternal fracture itself does not imply other major life-threatening conditions.

Pathophysiology

During rapid deceleration from a frontal impact, the forward thrust of the body against the fixed seat belt across the sternum can result in a fracture. The location of the sternal fracture varies depending on the position of the belt, patient size, the magnitude of the impact, and the vector of the forces.

Clinical Features

Patients with sternal fractures typically present with a history compatible with the injury, and anterior chest pain, point tenderness over the sternum, ecchymosis, soft tissue swelling, or palpable deformity.

Diagnostic Testing

When sternal fracture is suspected after a relatively minor mechanism of injury (eg, ground level fall or punch to the chest), posteroanterior and lateral chest radiography is sufficient to establish the diagnosis and for evaluation of the pulmonary structures. However, when more significant traumatic signs or symptoms are present (as per the NEXUS-Chest CT criteria) or when plain radiography shows a displaced fracture or possible evidence of intrathoracic injury, we recommend obtaining a chest CT scan. Results will guide management of the sternal fracture and any associated mediastinal or other intrathoracic injuries. Notably, there are also specific ultrasound views during, or in addition to, evaluation by extended focused assessment with sonography in trauma (E-FAST) that may be more sensitive than plain radiography for sternal fracture.
Management

Treatment consists of providing adequate analgesia, as for rib fractures. In the absence of associated injuries, most patients with isolated sternal fractures who can achieve adequate pain control with oral medications can be safely discharged home. A small subset of patients with more severe sternal fractures may have severe pain and develop respiratory compromise or nonunion. These patients are best referred for operative fixation.

NONPENETRATING BALLISTIC INJURY

Principles

Background and Importance

Many law enforcement officers, emergency medical services personnel, and private security guards wear lightweight synthetic body armor for protection against gunshot injury. In addition, there have been a number of reports of armed robbers wearing such vests in anticipation of exchanging gunfire with police or security personnel. These vests are “bullet resistant” rather than “bulletproof,” depending on the weapon being used against them. They are composed of many different combinations of synthetic fibers such as Kevlar, and so wearers who are shot often nonpenetrating ballistic injuries rather than gunshot wounds.

Another type of nonpenetrating ballistic injury is caused by rubber bullets and beanbag shotgun shells. Rubber bullets have been used for many years by police agencies throughout the world for crowd dispersal and for nonlethal use of force. Beanbag shotgun shells are nylon bags filled with pellets, which are fired from a standard shotgun. Both of these projectiles have the potential to cause serious injury despite their classification of “nonmetal” or “less-than-lethal” use of force.

Pathophysiology

Bullet-resistant vests are usually capable of stopping penetration by the low-velocity missiles of most handguns, but the kinetic energy of the missile can be transmitted through the layers of protective cloth or armor and produce significant injury without penetration. The heart, liver, spleen, lung, and spinal cord are vulnerable to nonpenetrating ballistic injury that may occur despite innocent-appearing skin lesions.

Clinical Features

Patients who have been shot with “less-than-lethal projectiles” or with standard bullets while wearing bullet-resistant vests usually have erythema, ecchymosis, and marked tenderness to palpation over the affected area. There may be a projectile, such as a beanbag, still located in the wound. The area of tenderness and surrounding structures should be carefully palpated to identify any subcutaneous emphysema, crepitus, or bony step-offs.

Diagnostic Testing

Most patients with nonpenetrating ballistic injury do not require testing beyond a thorough physical examination. Those in whom there is concern for retained foreign body or underlying injury may need ultrasound examination, chest x-ray, or CT scan (as they might with other blunt trauma). However, patients with only superficial ecchymoses without clinical signs or symptoms of rib fracture, pneumothorax, hemothorax, or intrapleural/peritoneal penetration frequently require no additional testing.

Management

In patients in whom underlying injury has been excluded or it is of low clinical probability, management of nonpenetrating ballistic injury focuses on wound care, either of the ecchymotic area or of the superficial abrasion/laceration. Underlying injuries, when present, should be managed as noted elsewhere in this chapter.

Disposition

It is recommended that patients with all but the most superficial nonpenetrating ballistic injuries to the chest be observed closely for 4 to 6 hours to detect internal injuries that may manifest in a delayed manner.

PULMONARY INJURIES

PULMONARY CONTUSION AND LACERATION

Principles

Background and Importance

Pulmonary contusion is reported to be present up to 75% of patients with significant blunt chest trauma, most often from MVCs with rapid deceleration. Pulmonary contusion can also be caused by high-velocity missile wounds and the high-energy shock waves of an explosion in air or water.

In addition to contusions, the lungs can also sustain lacerations. Although they are most often lacerated from penetrating injury, they may also be injured by the inward projection of a fractured rib or avulsion of a pleural adhesion.

Pathophysiology

Pulmonary contusion is caused by an impact to the lung parenchyma followed by alveolar edema and hemorrhage but without an accompanying pulmonary laceration. The early diagnosis of pulmonary contusion is important if treatment is to be successful. Since its onset may be insidious, it should be suspected from a history of a high mechanism of injury (eg, a fall from height, an MVC, and other forms of significant trauma) rather than the initial chest radiograph.

Clinical Features

The clinical manifestations include dyspnea, tachypnea, cyanosis, tachycardia, hypotension, and chest wall bruising. There are no specific signs for pulmonary contusion or laceration, but hematysis may be seen. Moist rales or absent breath sounds may be heard on auscultation. Palpation of the chest wall commonly reveals fractured ribs. If flail chest is discovered, pulmonary contusion is commonly present.

Surprisingly, many of the worst contusions occur in patients without rib fractures. It has been theorized that the more elastic chest wall in younger individuals transmits increased force to the thorax. Although isolated pulmonary contusions can exist, they are associated with extrathoracic injuries in the majority of patients.

Diagnostic Testing

Laboratory

Hypoxemia frequently occurs with pulmonary contusions, and is often detected by a decreasing pulse oximetry reading. In patients

...
Pneumothorax can be divided into three types depending on whether air has direct access to the pleural cavity: (1) simple, (2) communicating, and (3) tension.

**Simple Pneumothorax.** A pneumothorax is considered simple (Fig. 38.5) when there is no communication with the atmosphere or any shift of the mediastinum or hemidiaphragm resulting from the accumulation of air. Traumatic simple pneumothorax is most often caused by a fractured rib that is driven inward, lacerating the pleura. It may also occur without a fracture

**Pathophysiology**

**Simple Pneumothorax.** A pneumothorax is considered simple (Fig. 38.5) when there is no communication with the atmosphere or any shift of the mediastinum or hemidiaphragm resulting from the accumulation of air. Traumatic simple pneumothorax is most often caused by a fractured rib that is driven inward, lacerating the pleura. It may also occur without a fracture

**Principles**

**Background and Importance**

Pneumothorax, which is the accumulation of air in the pleural space, is a common complication of chest trauma. It is reported to be present in 15% to 50% of patients who sustain significant chest trauma and is invariably present in those with transpleural penetrating injuries.

**Management**

Treatment for pulmonary contusion is primarily supportive. As with flail chest, intubation and mechanical ventilation should be avoided if possible, because they are associated with an increase in morbidity, including pneumonia, sepsis, pneumothorax, hypercoagulability, and longer hospitalization. In the rare case in which one lung has been severely contused and is causing significant hypoxemia, consideration should be given to intubating and ventilating each lung separately with a dual-lumen endotracheal tube and two ventilators. This allows for the difference in compliance between the injured and the normal lung and prevents hyperexpansion of one lung and gradual collapse of the other.

Management of patients with pulmonary contusions should include the restriction of intravenous (IV) fluids (to maintain intravascular volume within strict limits) and comprehensive supportive care consisting of vigorous tracheobronchial toilet, suctioning, and pain relief. These maneuvers may preclude the need for ventilator support and allow a more selective approach to both flail chest and pulmonary contusion.

Patients sustaining the force necessary to inflict a pulmonary contusion may also have pulmonary lacerations. Most of these are minor and rarely life-threatening, and they can usually be treated with continuous oxygen therapy, observation, or tube thoracostomy. Severe lacerations are associated with hemopneumothorax, multiple displaced rib fractures, and hemothysis. Often, these life-threatening lacerations require thoracotomy with resection or tracheotomy to control bleeding.

**PNEUMOTHORAX**

**Principles**

**Background and Importance**

Pneumothorax, which is the accumulation of air in the pleural space, is a common complication of chest trauma. It is reported to be present in 15% to 50% of patients who sustain significant chest trauma and is invariably present in those with transpleural penetrating injuries.

**Pathophysiology**

Pneumothorax can be divided into three types depending on whether air has direct access to the pleural cavity: (1) simple, (2) communicating, and (3) tension.

Simple Pneumothorax. A pneumothorax is considered simple (Fig. 38.5) when there is no communication with the atmosphere or any shift of the mediastinum or hemidiaphragm resulting from the accumulation of air. Traumatic simple pneumothorax is most often caused by a fractured rib that is driven inward, lacerating the pleura. It may also occur without a fracture

**Management**

Treatment for pulmonary contusion is primarily supportive. As with flail chest, intubation and mechanical ventilation should be

Radiology

Typical radiographic findings can begin to appear within minutes of injury and range from patchy, irregular, alveolar infiltrate to frank consolidation (Fig. 38.4). Although these changes may be present on the initial examination, they are almost always present within 6 hours. The rapidity of changes on chest x-ray visualization usually correlates with the severity of the contusion or laceration. Pulmonary contusion should be differentiated from acute respiratory distress syndrome (ARDS), with which it is often confused because the radiographic appearance of the two conditions may be similar. Contusion usually manifests within minutes of the initial injury, is usually localized to a segment or a lobe, is often apparent on the initial chest study, and tends to last 48 to 72 hours. ARDS is diffuse, and its development is usually delayed, often apparent on the initial chest study, and tends to last 48 to 72 hours.

Radiography

Plain chest radiographs, and one recent study found that isolated pulmonary contusions seen on CT only had a mortality of only 2.6% (compared to 4.7% for all patients with pulmonary contusion). The increased frequency of CT scans for blunt trauma patients has resulted in a corresponding increase in the diagnosis of pulmonary contusions and lacerations. CT scans have been shown to detect at least twice as many pulmonary contusions as plain radiographs, and one recent study found that isolated pulmonary contusions seen on CT only had a mortality of only 2.6% (compared to 4.7% for all patients with pulmonary contusion). The increased frequency of CT scans for blunt trauma patients has resulted in a corresponding increase in the diagnosis of pulmonary contusions and lacerations. CT scans have been shown to detect at least twice as many pulmonary contusions as plain radiographs, and one recent study found that isolated pulmonary contusions seen on CT only had a mortality of only 2.6% (compared to 4.7% for all patients with pulmonary contusion).
when the impact is delivered at full inspiration with the glottis closed, leading to a tremendous increase in intra-alveolar pressure and the subsequent rupture of the alveoli. A penetrating injury, such as a gunshot or stab wound, may also produce a simple pneumothorax if there is no free communication with the atmosphere (Fig. 38.6).

**Communicating Pneumothorax.** A communicating pneumothorax (Fig. 38.7) is associated with a defect in the chest wall and most commonly occurs in combat injuries. In the civilian sector, this injury is typically secondary to gunshot wounds. Air can sometimes be heard flowing sonorously in and out of the defect, prompting the term “sucking chest wound.” The loss of chest wall integrity causes the involved lung to paradoxically collapse on inspiration and expand slightly on expiration, forcing air in and out of the wound. This results in a large functional dead space for the normal lung and, together with the loss of ventilation of the involved lung, produces a severe ventilatory disturbance.

**Tension Pneumothorax.** The progressive accumulation of air under pressure within the pleural cavity, with shift of the mediastinum to the opposite hemithorax and compression of the contralateral lung and great vessels, is the constellation of findings in tension pneumothorax (Figs. 38.8 and 38.9). It occurs when the injury acts like a one-way valve, prevents free bilateral communication with the atmosphere, and leads to a progressive increase of intrapleural pressure. Air enters on inspiration but cannot exit with expiration. The resulting shift of mediastinal contents compresses the vena cava and distorts the cavoatrial junction, leading to decreased diastolic filling of the heart and subsequent decreased cardiac output. These changes result in the rapid onset of hypoxia, acidosis, and shock.

**Clinical Features**
Shortness of breath and chest pain are the most common presenting complaints of pneumothorax. The patient’s appearance is highly variable, ranging from acutely ill with cyanosis and tachypnea to misleadingly healthy. The signs and symptoms are not always correlated with the degree of pneumothorax. The physical examination may reveal decreased or absent breath sounds and hyper-resonance over the involved side as well as subcutaneous emphysema, but small pneumothoraces may not be detectable on physical examination.

Patients with tension pneumothorax become acutely ill within minutes and develop severe cardiovascular and respiratory distress. They are dyspneic, agitated, restless, cyanotic, tachycardic, and hypotensive and display decreasing mental activity. The cardinal signs of tension pneumothorax are tachycardia, hypotension, oxyhemoglobin desaturation, jugular venous distention (JVD), and absent breath sounds on the ipsilateral side. However, JVD may not reliably be present with massive blood loss.

**Diagnostic Testing**
Because intrapleural air tends to collect at the apex of the lung, the initial chest radiograph should be an upright full inspiratory film if the patient’s condition permits. An upright film will often reveal small pleural effusions that are not visible on supine films, and it also allows better visualization of the mediastinum. Although the chest radiograph has traditionally been the preferred initial study for diagnosing a simple pneumothorax, several studies have found that ultrasound has greater sensitivity for pneumothorax than chest radiography. During the focused assessment with sonography in trauma (FAST) examination, pneumothorax will be detected well before chest radiography is performed. This may be particularly critical in the hypotensive state.
Simple Pneumothorax

Treatment of a simple pneumothorax depends on its cause and size. Small isolated apical pneumothoraces due to stab wounds may be observed without intervention. However, this conservative method seldom has application in multisystem trauma, and a chest tube should be inserted immediately upon any sign of deterioration.

Occult Pneumothorax

A pneumothorax that is absent on the initial chest radiograph but is identified on subsequent chest or abdominal CT is called an occult pneumothorax. Occult pneumothorax is being diagnosed more frequently given the increased use of CT (Fig. 38.10).16-18

Management

An asymptomatic patient who suffers a low-velocity penetrating trauma (typically a stab wound) and who has negative initial imaging can be safely observed, typically for 6 hours.16 If the initial imaging was a CT scan, the patient may be safely discharged after the period of observation. If the initial imaging was via x-ray, a delayed chest x-ray should be performed prior to discharge.

Simple Pneumothorax

Treatment of a simple pneumothorax depends on its cause and size. Small isolated apical pneumothoraces due to stab wounds may be observed without intervention. However, this conservative method seldom has application in multisystem trauma, and a chest tube should be inserted immediately upon any sign of deterioration.

Similarly, small occult pneumothoraces found only on CT scan in hemodynamically stable patients without symptoms can be managed with observation and do not need treatment, even if the patient is placed on positive-pressure ventilation.17-19

Any moderate to large pneumothorax should be treated with a chest tube. The indications for tube thoracostomy (chest tube) are listed in Box 38.2. The preferred site for insertion is the fourth or fifth intercostal space at the midaxillary line. This lateral placement of the tube is preferred not only because it is more efficient, but also because it does not produce an easily visible cosmetic defect, as does the anterior site at the second interspace at the midclavicular line. With multisystem trauma in which hemothorax is likely, a large chest tube (36-F to 40-F in adults and 16-F to 32-F in children) should be used. Conversely, spontaneous pneumothoraces or those due to minor or isolated injuries can be treated with smaller chest tubes.

Fig. 38.8. Tension pneumothorax seen in intubated patient.

Fig. 38.9. Resolution of the tension pneumothorax shown in Figure 38.7 with placement of a left-sided tube thoracostomy.

Fig. 38.10. Occult pneumothorax. Large left-sided pneumothorax visible on chest computed tomography (CT) scan, which was not visible on chest x-ray film.

**BOX 38.2**

**Indications for Tube Thoracostomy**

- Traumatic cause of pneumothorax (except asymptomatic, apical pneumothorax)
- Moderate to large pneumothorax
- Respiratory symptoms regardless of size of pneumothorax
- Increasing size of pneumothorax after initial conservative therapy
- Recurrence of pneumothorax after removal of an initial chest tube
- Patient requires ventilator support
- Patient requires general anesthesia
- Associated hemothorax
- Bilateral pneumothorax regardless of size
- Tension pneumothorax

Care is taken to be certain the vent holes along the side of the tube are all inside the chest cavity. A radiopaque line along the side of the tube with interruptions at these drainage holes helps greatly in radiographically interpreting tube position. The tube should be attached to a water seal drainage system that allows reexpansion of the pneumothorax. If there is significant air leak or a large hemothorax, the tube may be connected to a source of constant vacuum at 20 to 30 cm H₂O for more rapid reexpansion.

Tube thoracostomy does have some potentially serious complications, including the formation of a hemothorax, pulmonary edema, bronchopleural fistula, pleural leaks, empyema, subcutaneous emphysema, infection, intercostal artery laceration, contralateral pneumothorax, and parenchymal injury.26,27 A recent meta-analysis was unable to find sufficient evidence for or against the use of empirical antibiotics with all tube thoracostomy placements to prevent empyema or pneumonia, especially those needed for spontaneous pneumothoraces. However, for patients with multisystem trauma or hemothorax, the data was suggestive of a benefit. We recommend routine intravenous antibiotic administration in these patients, specifically cefazolin 1 to 2 g given prior to—or within 1 hour of—chest tube insertion. Vancomycin (1 g) or clindamycin (600 mg) are appropriate alternatives in patients in whom cephalosporins are inappropriate.22

Communicating Pneumothorax

For a patient with a communicating pneumothorax in the out-of-hospital setting, the defect should be covered immediately, which helps convert the condition to a closed pneumothorax, eliminating the major physiologic abnormality. Either a partially occlusive dressing or a commercial vented chest seal can be applied; care should be taken to continually assess for conversion of the injury to a tension pneumothorax, especially in patients who are intubated and undergoing positive-pressure ventilation.25,26 The wound should never be packed, because the negative pressure during inspiration can suck the dressing into the chest cavity. These considerations are not as important once the patient is in the ED, where formal tube thoracostomy can be performed. Positive-pressure ventilation can then be initiated, if needed, without the fear of producing a tension pneumothorax, and the patient can be prepared for definitive surgical repair.

Tension Pneumothorax

When the diagnosis of tension pneumothorax is suspected clinically, the pressure should be relieved immediately with needle thoracostomy, which is performed by inserting a large-bore (14- or 16-gauge) catheter, at least 5 cm in length, through the fourth or fifth interspace laterally or the second or third interspace anteriorly on the involved side. Recent studies have suggested that some catheters may not be of sufficient length to penetrate the pleural space.25,27 So, we recommend the lateral approach if it is accessible. This method can be easily performed in the field, allowing vital signs to improve during transport or preparation for a tube thoracostomy.28

In the ED, it may be just as expeditious to insert a chest tube (or even perform a “finger thoracostomy,” without actually inserting the chest tube) as it is to perform a needle thoracostomy, depending on the availability of equipment. Regardless, even if a needle thoracostomy is performed on a patient with suspected tension pneumothorax in the ED, a chest tube should emergently follow.

The intubated patient in the ED who is receiving positive-pressure ventilation and external cardiac compressions is at particular risk for developing tension pneumothorax. Fractured ribs from cardiopulmonary resuscitation (CPR) can penetrate lung parenchyma and cause pneumothorax. Positive-pressure ventilation then increases intrapleural pressure and produces a tension pneumothorax. The earliest sign of this complication is an increase in resistance to ventilation. If the patient has vital signs, the blood pressure will fall and the central venous pressure (CVP) will rise. Misplacement of an endotracheal tube does not result in tension pneumothorax but, rather, asymmetry of breath sounds. If tension pneumothorax is suggested, the clinician should proceed with empirical emergent therapy.

HEMOTHORAX

Principles

Background and Importance

Hemothorax, which is the accumulation of blood in the pleural space after blunt or penetrating chest trauma, is a common complication that may produce hypovolemic shock and dangerously reduce vital capacity. It is commonly associated with pneumothorax and extrathoracic injuries.

Pathophysiology

Hemorrhage from injured lung parenchyma is the most common cause of hemothorax, but this tends to be self-limited unless there is a major laceration. Specific vessels are less often the source of hemorrhage, with intercostal and internal mammary arteries causing hemothorax more often than hilar or great vessels. Bleeding from the intercostal arteries may be brisk, however, because they branch directly from the aorta.

Clinical Features

Depending on the rate and quantity of hemorrhage, varying degrees of hypovolemic shock will be manifested. Patients may present in respiratory distress and be tachycardic and hypoxic. Breath sounds may be diminished. The diagnosis should also be remembered as a potential complication of central line placement, and considered—along with pneumothorax—in patients who present with these symptoms after the procedure.

Diagnostic Testing

The upright chest radiograph remains the primary diagnostic study in the acute evaluation of hemothorax. A hemothorax is noted as meniscus of fluid blunting the costophrenic angle and tracking up the pleural margins of the chest wall when viewed on the upright chest x-ray film. Blunting of the costophrenic angles on upright chest radiograph requires at least 200 to 300 mL of fluid. The supine view chest film is less accurate but, unfortunately, is often the only film available because of the patient’s unstable condition. In the supine patient, blood layers posteriorly, creating a diffuse haziness that can be rather subtle (or appear to be a pulmonary contusion), depending on the volume of the hemothorax (Fig. 38.11). With massive hemothorax, the large volume of blood can create a tension hemothorax, with signs and symptoms of both obstructive and hemorrhagic shock (Fig. 38.12).

As is the case with pneumothoraces, ultrasound has greater sensitivity than supine chest radiography in the detection of hemothoraces.29 Given this, early bedside ultrasonography should routinely be performed in patients with thoracic trauma, regardless of findings on supine radiography. Additional imaging via chest CT (Fig. 38.13) should be performed if indicated by the NEXUS-Chest CT criteria as discussed earlier,1 because it may detect hemothorax or other associated injuries (Fig. 38.14).
monitoring of the blood loss, and serial chest radiographs help monitor lung reexpansion. A large-bore tube (36-F to 40-F) should be inserted in the fifth interspace at the anterior axillary line and connected to underwater seal drainage and suction (20 to 30 mL H$_2$O).

Although small hemothoraces may be observed in stable patients, a moderate hemothorax or any hemothorax in an unstable or symptomatic patient requires tube thoracostomy. Severe or persistent hemorrhage requires thoracostomy or open thoracotomy. Studies are required to better delineate the size of a hemothorax detected on CT scan that requires tube thoracostomy drainage.

Autotransfusion has been successfully used in tube thoracostomy. Autotransfusion also eliminates the risk of incompatibility reactions and transmission of certain diseases, such as hepatitis C. Because the majority of blood loss occurs immediately after tube thoracostomy placement, autotransfusion apparatus should be immediately available in the ED.

Close monitoring of the initial and ongoing rate of blood loss should be performed. Immediate drainage of more than 1500 mL of blood from the pleural cavity is considered an indication for urgent thoracotomy, as is a continued output of at least 200 mL/hr for 3 hours. General considerations for urgent thoracotomy are outlined in Box 38.3.

**TRACHEOBRONCHIAL INJURY**

**PRINCIPLES**

**Background and Importance**

Tracheobronchial injuries may occur with either blunt or penetrating injuries of the neck or chest. MVCs are the most frequent mechanism causing tracheobronchial injury, accounting for more than half of all cases.

Although there has been an increase in the occurrence of tracheobronchial disruption, it is still a relatively rare injury, occurring in fewer than 3% of patients with significant chest injury. Its
CHAPTER 38
Thoracic Trauma

DIAGNOSTIC TESTING

When tracheobronchial injury is suspected, bronchoscopy should be performed. Flexible endoscopic bronchoscopy is the most preferred and reliable means of establishing the diagnosis and determining the site and extent of the injury. However, CT scan has been shown to have high sensitivity in detecting tracheobronchial injury. Bronchopleural fistula (a communication between a bronchus and the lung parenchyma) can occur as a complication of tracheobronchial disruption and in some cases has been treated successfully via the fiberoptic bronchoscope. A mediastinal fluid collection, evidence of mediastinitis, or both may be noted on chest CT.

MANAGEMENT

If diagnostic bronchoscopy is performed, endotracheal intubation can be performed over the bronchoscope to ensure that the tube passes safely beyond the site of injury. Blind intubation should not be attempted. If intubating using a video laryngoscope (or associated mortality rate is reported to be approximately 10%, although mortality rates are significantly affected by associated injuries and the timing of diagnosis and surgical repair.

Pathophysiology

Tracheobronchial injuries caused by knife wounds develop almost exclusively from wounds in the cervical trachea (see Chapter 37), whereas gunshot wounds may damage the tracheobronchial tree at any point. Intrathoracic injury to the tracheobronchial tree occurs most commonly from blunt trauma. These injuries may result from direct blows, shearing stresses, or burst injury. A direct blow to the neck may crush the cervical trachea against the vertebral bodies and transect the tracheal rings or cricoid cartilage. Shear forces on the trachea will produce injury at the carina and the cricoid cartilage, which are its relatively fixed points.

Sudden deceleration of the thoracic cage pulls the lungs away from the mediastinum, producing traction on the trachea at the carina. When the elasticity of the tracheobronchial tree is exceeded, it ruptures. It has also been suggested that if the glottis is closed at the time of impact, the sudden increase in intrabronchial pressure will rupture the tracheobronchial tree. Regardless of the mechanism, more than 80% of these injuries occur within 2 cm of the carina.

CLINICAL FEATURES

Massive air leak through a chest tube, hemoptyis, and dramatic or increasing subcutaneous emphysema should suggest the diagnosis of major airway damage. Subcutaneous emphysema is typically the most common physical finding. Auscultation of the heart may reveal Hamman’s crunch if air tracks into the mediastinum. Hamman’s crunch is a crunching, rasping sound that is synchronous with the pulse and is best heard over the precordium. It is the result of the heart beating against air-filled tissues. Patients with tracheobronchial disruption have one of two distinct clinical pictures. In the first group of patients, the wound opens into the pleural space, producing a large pneumothorax. A chest tube fails to evacuate the space and reexpand the lung, and there is continuous bubbling of air (persistent leak) in the underwater seal device (Fig. 38.15).

In the second group of patients, there is complete transection of the tracheobronchial tree but little or no communication with the pleural space. A pneumothorax is usually not present. The peribronchial tissues support the airway enough to maintain respiration, but within 3 weeks, granulation tissue will obstruct the lumen and produce atelectasis. These patients are relatively free of symptoms at the time of injury; but weeks later, they have unexplained atelectasis or pneumonia. Radiographic signs in either group of patients are pneumomediastinum, extensive subcutaneous emphysema (Fig. 38.16), pneumothorax, fracture of the upper ribs (first through fifth), air surrounding the bronchus, and obstruction in the course of an air-filled bronchus.

BOX 38.3

Indications for Thoracotomy

Initial thoracostomy tube drainage is more than 20 mL of blood per kilogram.
Persistent bleeding at a rate greater than 7 mL/kg/hr is present.
Increasing hemothorax seen on chest x-ray films.
Patient remains hypotensive despite adequate blood replacement, and other sites of blood loss have been ruled out.
Patient decompensates after initial response to resuscitation.

Fig. 38.15. Penetration of lung parenchyma by tube thoracostomy (arrow), with large residual pneumothorax, visible on computed tomography (CT) scan.

Fig. 38.16. Multiple rib fractures with extensive subcutaneous emphysema (arrow), with no pneumothorax seen.
conventional laryngoscope), the tube is advanced slowly and gently to avoid creating a false passage or converting a partial tracheal tear to a complete tear.

The standard treatment for tracheobronchial injury has been thoracotomy with intraoperative tracheostomy and surgical repair of the disrupted airway. However, conservative medical treatment of such injuries can be considered for patients with tracheal tears less than 2 cm and without esophageal prolapse, mediastinitis, or massive air leakage.30

DIAPHRAGMATIC INJURY

**PRINCIPLES**

**Background and Importance**

Diaphragmatic rupture is present in 1% to 6% of major thoracic injuries. Diaphragmatic rupture occurs most commonly after blunt thoracoabdominal trauma, such as occurs in MVCs or falls from heights, but can also occur from penetrating trauma.

**Pathophysiology**

Diaphragmatic hernia is a herniation of abdominal structures into the thoracic cavity through a defect on the diaphragm, with a potential risk of strangulation of abdominal viscera, especially the small bowel. Signs and symptoms may not occur during the initial admission and may be delayed for as long as months to years, with a significant mortality rate.

Three-quarters of cases of diaphragmatic rupture secondary to blunt trauma occur on the left side, the remainder on the right, presumably due to the protective effect of the liver on the right side. Only about 5% of cases are bilateral. With penetrating injury, diaphragmatic injury occurs at the site of the penetration but may be occult.

In cases of blunt injury, the raised pressure within the abdominal cavity causes the diaphragmatic tear, and a pressure difference of generally 5 to 10 mm Hg forces the abdominal organs through the diaphragmatic defect. Because blunt trauma can cause multiple organ injuries, these coexisting injuries can mask the more silent diaphragmatic injuries, and diaphragmatic rupture may be initially overlooked. Over time, negative intrathoracic pressure generated by inspiration tends to draw abdominal contents into the thorax. This effect is lost with the use of intubation and positive-pressure ventilation.

**DIAGNOSTIC TESTING**

Accurate diagnosis of traumatic diaphragmatic hernia is essential because prompt surgical repair is the treatment of choice, but plain chest radiography alone is poorly sensitive for diaphragm rupture.

In patients with blunt trauma, CT examination of the abdomen and chest can be very useful for the evaluation of diaphragmatic injury, although injury site and type affect its sensitivity. Nevertheless, CT can demonstrate findings consistent with diaphragmatic injury, including diaphragmatic discontinuity, intrathoracic herniation of abdominal contents, and waist-like constriction of abdominal viscera (the “collar sign”).

In patients with penetrating left thoracoabdominal trauma, the incidence of herniation of abdominal contents is sufficiently high that thoracoscopy or laparoscopy is recommended for the diagnosis and repair of a diaphragmatic injury. Even in patients with right-sided penetrating lesions (which do not typically result in herniation because of the protective effect of the dome of the liver), evaluation of both sides of the diaphragm with laparoscopy or thoracoscopy is recommended.

**MANAGEMENT**

Diaphragmatic injuries may be markers of severity and predictors of serious associated injuries in trauma and should be surgically repaired. The treatment of choice is surgery. CT scan should identify the site and extent of herniation, herniated organs, complications, and damage to associated organs. Although they are not without complications, laparoscopy and thoracoscopy may be used for diaphragmatic hernia repair.

The incidence of diaphragmatic involvement after penetrating left-sided thoracoabdominal injury is high, making nonoperative, expectant management of these patients potentially unsafe.

**CARDIOVASCULAR TRAUMA**

**BLUNT CARDIAC TRAUMA**

Blunt cardiac injury usually results from high-speed MVCs in which the chest wall strikes the steering wheel. Other causes, such as falls from heights, crushing injuries, blast injuries, and direct blows, are less common. The diagnosis of a blunt injury to the heart remains elusive because of the usual concomitant serious injuries to other body organs and, more important, because there is no gold standard for making the diagnosis.

The importance of detecting blunt myocardial injury lies in the recognition of associated potentially fatal complications. Life-threatening dysrhythmias, conduction abnormalities, congestive heart failure, cardiogenic shock, hemopericardium with tamponade, cardiac rupture, valvular rupture, intraventricular thrombi, thromboemolic phenomena, coronary artery occlusion, ventricular aneurysms, and constrictive pericarditis have all been reported as complications.

Blunt cardiac trauma may be viewed as part of a continuous spectrum (ie, myocardial concussion, contusion, infarction, and rupture). Myocardial concussion occurs when a blunt injury to the interior chest produces a "stun" response in the myocardium. No permanent cellular injury occurs, but transient clinical effects may result. Myocardial contusion is the least severe form of injury that can be demonstrated pathologically. Cellular injury occurs with extravasation of red blood cells into the muscle wall, along with localized myocardial cellular necrosis. Permanent myocardial damage is rare. Infarction typically occurs with traumatic occlusion or disruption of a coronary artery. Cardiac rupture is obviously the most severe form of blunt cardiac injury.

**MYOCARDIAL CONCUSSION**

**Principles**

**Background and Importance**

The terms myocardial concussion or commotio cordis are used to describe an acute form of blunt cardiac trauma that is usually produced by a sharp, direct blow to the midanterior chest that stuns the myocardium and results in brief dysrhythmia, hypotension, and loss of consciousness. It is a rare event and primarily occurs in adolescents, especially those playing sports involving hard spherical objects (eg, baseballs, hockey pucks, and so on).

**Pathophysiology**

Animal models of commotio cordis have determined that it is much more likely to occur if the impact occurs during early ventricular repolarization.31 Additionally, flat objects and softer balls (eg, tennis or soccer) are less likely to cause commotio cordis than smaller balls.32 Once this dysrhythmia occurs, it can result in a non-perfusing rhythm, such as asystole or ventricular
fibrillation, and irreversible cardiac arrest. There are, however, a number of documented cases of successful resuscitation with both rapid provision of CPR and the use of an automated external defibrillator (AED).

Clinical Features

Commotio cordis has a characteristic mechanism (blunt chest trauma) and presentation (sudden collapse). Notably, the disease itself is defined by a lack of structural cardiac damage, and so more severe trauma (such as that necessary to cause cardiac contusion or rupture, as described later) is incongruent with the diagnosis.

Diagnostic Testing

Laboratory Tests and Electrocardiogram

Patients who present with the characteristic mechanism and presentation above and who have shockable rhythms on electrocardiogram (ECG) (or who were defibrillated by an AED) can be presumed to have commotio cordis if there is no evidence of structural heart damage on echocardiography or CT. Laboratory evaluation of serum electrolyte and cardiac biomarker levels may identify additional contributors to their presentation, but these will typically be normal.

Management

The initial treatment of patients with commotio cordis should follow standard advanced cardiac life support (ACLS) algorithms, ideally with initiation of bystander CPR and early defibrillation (especially at sporting events). Barring any other more severe cardiac injuries (discussed later), commotion cordis does not require any specific interventions.

Disposition

In patients who survive the dysrhythmia of commotio cordis and are not found to have more severe traumatic cardiac injury, a short period of observation is appropriate. Although there is a paucity of evidence as to the duration of this observation period, we recommend 6 to 12 hours of telemetry monitoring. After this, patients may be discharged, although they should not return to play until additional outpatient cardiac testing (eg, stress testing, cardiac magnetic resonance imaging [MRI], and pharmacologic testing for primary conductive disorders, if indicated) is performed.

MYOCARDIAL CONTUSION

Principles

Background and Importance

Myocardial contusion is a very poorly understood and nebulous condition. Decades of research and widely varied clinical practice have failed to produce a consensus regarding its diagnosis, complication rate, and proper disposition.

Pathophysiology

Several mechanisms have been postulated by which the heart may be injured in cases of blunt trauma. A direct blow to the chest transmits energy through the ribs to the spine. When a large force is applied to the chest wall, the sternum is displaced posteriorly and the heart is compressed between the sternum and vertebrae or an elevated diaphragm. Either can presumably result in cardiac injury. Increased intrathoracic pressure from a direct blow to the chest may contribute to the injury. In addition, compression of the abdomen and pelvis may displace abdominal viscera upward and result in cardiac injury.

Clinical Features

Myocardial contusion manifests clinically as a spectrum of injuries of varying severity. Although the majority of patients with myocardial contusion have external signs of thoracic trauma (eg, contusions, abrasions, palpable crepitus, rib fractures, or visible flail segments), the absence of identifiable thoracic injury decreases the likelihood of myocardial contusion but does not exclude it. Virtually every known intrathoracic and chest wall injury has been associated with myocardial contusion. The most sensitive but least specific sign of myocardial contusion is sinus tachycardia, which is present in approximately 70% of patients with documented myocardial contusions and is a very common vital sign in trauma patients. A reduction in cardiac output, which can be clinically insignificant or manifest as pronounced cardiogenic shock, may occur in patients with significant cardiac contusion.

Diagnostic Testing

Unfortunately, there is not an agreed upon gold standard diagnostic definition for myocardial contusion. Clinical evidence is often nonspecific, especially in the setting of multiple traumas. Many tests and definitions have been proposed over the years, but none has emerged as definitive.

Laboratory Tests and Electrocardiogram

Electrocardiogram. Because of its anterior position in the thorax and proximity to the sternum, the right ventricle is far more likely to be injured than the left ventricle. The standard 12-lead ECG is relatively insensitive to right ventricular damage, as demonstrated by pathologic evidence of cellular damage in patients with normal ECGs. A cardiac contusion usually results in moderate right ventricular damage with only minor electrical changes, which can easily be missed on ECG. Right-sided ECGs (the addition of V4R) have not been found to be of any benefit.

The ECG for patients with myocardial contusion often shows evidence of dysrhythmia, conduction disturbance, or ischemia. Dysrhythmias or ECG changes also can be caused by significant hypoxia as a result of pulmonary injuries or blood loss, which resolve once the hypoxemia or blood loss has been corrected.

A few cases of delayed life-threatening dysrhythmia have been reported up to 12 hours after injury, and patients may develop less lethal dysrhythmias up to 72 hours after injury. The onset of ECG changes may be delayed up to 48 hours after injury, but all ECG changes usually resolve in 4 to 60 days. The presence of ECG abnormalities is neither specific enough to confirm the diagnosis of myocardial contusion nor reliable enough to predict subsequent complications, but a newly abnormal ECG (arrhythmia/heart block or ischemic changes) warrants admission for continuous ECG monitoring.

Cardiac Biomarkers. Because creatine kinase (CK) is nonspecifically increased in trauma patients owing to associated skeletal muscle injury, and CK-MB levels have also been found to be falsely elevated in multi-trauma patients, the troponin assay is the preferred cardiac biomarker for testing.

The combination of a normal troponin level and a normal 12-lead ECG has a negative predictive value sufficient to “rule out” myocardial contusion, and these patients do not need any other evaluation or monitoring specific for myocardial contusion.
Imaging

Although echocardiography provides a means to directly visualize cardiac structures and chambers and can be very useful to rule out structurally significant myocardial injuries (eg, wall motion or valvular abnormalities), it should not be routinely used as a primary screening modality for blunt cardiac injury. Rather, echocardiography should be reserved for patients in whom myocardial contusion is suspected (based on ECG or troponin level) and who have unexplained hypotension or arrhythmias.

Management

Treatment of a suspected myocardial contusion is similar to that of a myocardial infarction (MI): saline lock (if IV fluids are not otherwise indicated), cardiac monitoring, administration of oxygen if hypoxic, and analgesic agents. Dysrhythmias are typically transient and do not require treatment. Serious dysrhythmias, such as ventricular tachycardia or atrial flutter should be treated with appropriate medications as per current ACLS guidelines. No data exist to support prophylactic dysrhythmia suppression. Measures should be taken to treat and prevent any conditions that increase myocardial irritability (eg, metabolic acidosis). Thrombolytic agents and aspirin are contraindicated in the setting of acute trauma. In rare instances, there may be an acute MI associated with trauma, which can arise from lacerations or blunt injury to the coronary arteries. These cases should be managed by percutaneous coronary intervention (PCI), with cardiothoracic surgery for definitive repair as indicated.

In the setting of depressed cardiac output caused by suspected or confirmed myocardial contusion, judicious fluid administration to augment preload is warranted (eg, 200 to 250 mL boluses every 15 minutes to a maximum of 1 to 2 L). A dobutamine infusion may be useful once preload has been optimized. While intra-aortic balloon counterpulsation has been used successfully in refractory cardiogenic shock, the priority is to ascertain that the decreased cardiac output is not the result of other undiagnosed traumatic injuries, particularly aortic rupture.

The prognosis of a patient with myocardial contusion depends on the character and magnitude of the initial trauma, the size and location of the contusion, the preexisting condition of the coronary arteries, and, most importantly, with the number of associated serious injuries. Recovery without complications is the usual course.

Disposition

Patients with suspected myocardial contusion who have a normal troponin level and a normal ECG do not have the diagnosis. Myocardial contusions resulting in ECG changes or troponin elevations necessitate telemetry observation or in-hospital monitoring, depending on the patients’ other injuries. Markedly abnormal ECGs, troponin elevations, or hypotension warrant echocardiography and cardiology consultation.

MYOCARDIAL RUPTURE

Principles

Background and Importance

High-speed MVCs are responsible for most cases of traumatic myocardial rupture, which is almost always fatal. Approximately one-third of these patients have multiple chamber rupture, and one-fourth have an associated ascending aortic rupture. Approximately 20% of patients survive at least 30 minutes, theoretically long enough to get them to the cardiac surgery operating room if the injury is recognized immediately and the center is capable.

Anatomy and Physiology

Myocardial rupture refers to an acute traumatic perforation of the ventricles or atria, but it may also include a pericardial rupture or laceration or rupture of the interventricular septum, interatrial septum, chordae, papillary muscles, valves, and lacerated coronary arteries. A delayed rupture of the heart may also occur weeks after nonpenetrating trauma, probably as a result of necrosis of a contused or infarcted area of myocardium.

The chambers most commonly involved in cardiac rupture are the ventricles, with right ventricular rupture being most common. Ruptures of the atria are less common, with right atrial rupture being more common than left. Multiple chamber involvement occurs in 20% of patients. Twenty percent of nonsurvivors have concomitant aortic rupture.

Pathophysiology

A rupture occurs during closure of the outflow tract when there is ventricular compression of blood-filled chambers by a pressure sufficient to tear the chamber wall, septum, or valve. This is the most likely mechanism for ventricular rupture when injury occurs in diastole or early systole concomitant with maximal ventricular distention. The atria are most susceptible to rupture by sudden compression in late systole when these chambers are maximally distended with venous blood and the atrial ventricular valves are closed. Other proposed mechanisms of rupture include: (1) deceleration shearing stresses acting on the “fixed” attachment of the inferior and superior vena cava at the right atrium; (2) upward displacement of blood and abdominal viscera from blunt abdominal injury that causes a sudden increase in intracardiac pressure; (3) direct compression of the heart between the sternum and vertebral bodies; (4) laceration from a fractured rib or sternum; and (5) complications of a myocardial contusion, necrosis, and subsequent cardiac rupture.
